Neuropathic pain is a clinical manifestation of nerve injury difficult to treat even with potent analgesic compounds. Here, we used different lines of genetically modified mice to clarify the role played by CB$_2$, cannabinoid receptors in the regulation of the central immune responses leading to the development of neuropathic pain. CB$_2$ knock-out mice and wild-type littermates were exposed to sciatic nerve injury, and both genotypes developed a similar hyperalgesia and allodynia in the ipsilateral paw. Most strikingly, knock-outs also developed a contralateral mirror image pain, associated with an enhanced microglial and astrocytic expression in the contralateral spinal horn. In agreement, hyperalgesia, allodynia, and microglial and astrocytic activation induced by sciatic nerve injury were attenuated in transgenic mice overexpressing CB$_2$ receptors. These results demonstrate the crucial role of CB$_2$ cannabinoid receptor in modulating glial activation in response to nerve injury. The enhanced manifestations of neuropathic pain were replicated in irradiated wild-type mice reconstituted with bone marrow cells from CB$_2$ knock-outs, thus demonstrating the implication of the CB$_2$ receptor expressed in hematopoietic cells in the development of neuropathic pain in the spinal cord.

Key words: CB$_2$, cannabinoid receptor; microglia; astrocytes; neuropathic pain; bone marrow chimera; neuroinflammation

Introduction

The interest in the medical use of cannabinoid ligands has greatly increased in the last few years. Two cannabinoid receptors, CB$_1$ and CB$_2$ (Matsuda et al., 1990; Munro et al., 1993), have been extensively studied to clarify their involvement in several pathophysiological situations in which cannabinoid ligands could be potential therapeutic agents, including pain management. Indeed, cannabis derivatives have been used for centuries as analgesic compounds, and cannabinoid agonists have been reported to be effective on several animal models of acute and chronic pain (Pertwee, 2001). However, the psychoactive effects of these agonists could mainly represent a serious limitation for their clinical use. CB$_2$ receptors, mainly located in the CNS (Tsou et al., 1998), seem to be selectively involved in cannabinoid psychoactive effects (Ledent et al., 1999; Zimmer et al., 1999). Interestingly, the activation of CB$_1$ receptors expressed in peripheral nociceptors but not in the CNS attenuates neuropathic pain in rodents (Agarwal et al., 2007). The identification of CB$_2$ receptors in glial cells (Zhang et al., 2003; Beltramo et al., 2006) has opened new therapeutic approaches for these ligands. CB$_2$ receptors have been also proposed to be present in neurons (Van Sickle et al., 2005), although this issue is still controversial. CB$_2$ receptor activation induces analgesic effects in several animal models (Beltramo et al., 2006; Ibrahim et al., 2006; Bingham et al., 2007; Gliblin et al., 2007), and selective CB$_2$ agonists could be potentially used as analgesic drugs, thus circumventing psychoactive side effects of CB$_1$ agonists (Whiteside et al., 2007).

In the spinal cord, CB$_2$ receptor expression was induced during neuropathic pain produced by peripheral nerve injury in parallel with the simultaneous expression of activated microglia (Zhang et al., 2003). Microglia seem to be involved in the development of neuropathic pain through the release of several cytokines, which are known to produce neuron sensitization in the spinal cord (DeLeo and Yezierski, 2001; Clark et al., 2007). Interestingly, CB$_2$ receptor stimulation has been reported to attenuate microglial activation (Ehrhart et al., 2005; Romero-Sandoval and Eisenach, 2007) and CB$_2$ agonists induce analgesic effects in neuropathic pain models (Ibrahim et al., 2003). Although these studies suggest a potential role for CB$_2$ receptors in the modulation of neuropathic pain, the mechanism underlying these analgesic ef-
fects and the exact involvement of CB2 receptors in the development of neuropathic pain has not been clarified yet. We have therefore now used genetically modified mice lacking (CB2−/−) (Buckley et al., 2000; Ofek et al., 2006) or overexpressing CB2 cannabinoid receptors to evaluate the participation of these receptors in the behavioral and histological consequences of the development of neuropathic pain after partial sciatic nerve injury. Additional experiments using irradiated wild-type (WT) (CB2+/+) mice receiving bone marrow transplantation from CB2−/− have been performed to identify the biological mechanisms involved in the regulation of neuropathic pain responses by CB2 receptors.

Materials and Methods

Animal experimental conditions. Animals were housed in groups of three to five and had ad libitum access to water and food. The housing conditions were maintained at 21 ± 1°C and 55 ± 10% relative humidity in a controlled light/dark cycle (light on between 8:00 A.M. and 8:00 P.M.). All experimental procedures and animal husbandry were conducted according to standard ethical guidelines (European Community Guidelines). All experimental procedures and animal husbandry were conducted according to the local ethical committee (Comité Ético Experimental Animal–Instituto Municipal de Asistencia Sanitaria/Universitat Pompeu Fabra, Bezirksregierung Köln). All experiments were performed under conditions of CB2 knock-out mice. Male and female CB2−/− mice and wild-type littersmates (CB2+/+) on a C57BL/6J congenic background (Buckley et al., 2000), ~3 months of age and weighing 23–29 g at the beginning of the experiments, were used.

Plasmid constructs and generation of transgenic mice overexpressing CB2. The open reading frame (ORF) of the murine CB2 receptor was isolated by PCR amplification from mouse brain mRNA, using primers which created an XhoI restriction enzyme site adjacent to the translation start and stop sites. The expression vector MoPrP.Xho (Watkins et al., 2003) was used for the production of transgenic mice. This vector contains the murine PrP ORF, exon 1, intron 1, exon 2, and 3′ untranslated sequences. The CB2 receptor ORF was cloned in exon 2 of MoPrP.Xho construct (Watkins et al., 2003). The PrP-CB2 transgene was excised from the plasmid vector with restriction endonuclease NorI leading to DNA fragments of 12 kb. Transgenic founders were crossed with outbred CD-1 mice for seven generations. The presence of the transgene was determined by PCR using specific primers again exon 2 of PrP (5′-CGAGC- CTCACCATGATGCG) and CB2 receptor (5′-AGCCACCGTTG-GAGCGCCGTG)...

Analysis of CB2 mRNA expression by real-time PCR. Mice were killed by cervical dislocation. Brains, and cervical and thoracic sections of the spinal cord were removed rapidly, frozen, and stored immediately at −80°C until use. Brain sections were cut at 50 µm at different levels containing the regions of interest: thalamus and periaqueductal gray (PAG). These sections were obtained according to Paxinos and Franklin (2001), mounted onto slides, and stored at −80°C until use. Sections were dissected following the method described by Palkovits (1983). Total RNA was extracted from brain punches and spinal cord sections using Ultraspec RNA (Biotecx). After DNase digestion, the reverse transcription was performed following the manufacturer’s instructions of Epicenter Technologies Corporation. Quantitative PCR was performed in three replicates using a Rotorgene 3000 Real Time Cycler (Corbett Research) and SYBR Green (Invitrogen) as a double-stranded DNA-specific fluorescent dye (Gutiérrez-Adán et al., 2004). Primers for transgenic quantification were the same as described above. Primers for the quantification of the expression of endogenous CB2 were 5′-TCTGGAAAGCC-CACCCGCACTTAG and 5′-CAAGCCACAGCATGAAACAGAG. The comparative CT method was used for quantification of expression levels (Gutiérrez-Adán et al., 2004). A GADPH cDNA was used as normalization control to ensure constant GADPH levels in all samples regardless of experimental conditions. One-way repeated-measures ANOVA (followed by multiple pairwise comparisons using Student–Newman–Keuls method) were used for the analysis of differences in mRNA expression assayed by quantitative reverse transcription–PCR.

Generation of bone marrow chimeric mice. Bone marrow (BM) cells were harvested by flushing tibias and femurs from 6- to 8-week-old CB2−/− or CB2+/+ male donor mice with PBS. Single-cell suspensions were prepared by filtering BM cells through a 100 µm cell strainer. CD45.1 congenic male recipient mice were given lethal total body irradiation (900 rad), and 24 h later were intravenously reconstituted with 5 × 106 BM cells. The animals received intraperitoneally 150 mg/kg amoxicillin and 15 mg/kg clavulanic in a volume of 0.1 ml/10 g for 10 d starting on the day of transfer. After 8 weeks of engraftment, the efficiency of the reconstruction was assessed by flow cytometric analysis of peripheral blood lymphocytes (PBLs). All mice were bleed from the tail vein and PBLs were analyzed by flow cytometry (FACS Canto Flow Cytometer; BD Biosciences; FlowJo analysis software; Tree Star) with monoclonal antibodies against CD45.1 and CD45.2 (BD Biosciences) to determine the degree of chimerism. Only BM-chimeric mice that showed >93% reconstitution efficiency with donor cells were chosen for the experiments. CB2−/− mice reconstituted with CB2+/+ BM are referred to as chimera-WT, and CB2+/+ animals reconstituted with CB2−/− BM are referred to as chimera-CB2.

Preparation of microglia. Brains and spinal cords were removed from perfused mice, and single-cell suspensions were generated and filtered through a 100 µm cell strainer. Percoll gradients of 30/37/70% were performed for fractionation of cells at 1000 × g for 30 min, and brain mononuclear cells were collected from the surface. Flow cytometry was performed as described for PBL analysis of animals.

Behavioral experiments. Hyperalgesia to noxious thermal stimulus (plantar test) and allodynia to cold (cold-plate test) and mechanical stimuli (von Frey stimulation model) were used as outcome measures of neuropathic pain. In the plantar test, the mean paw withdrawal latencies for the ipsilateral and contralateral hindpaws were determined from the average of three separate trials, taken at 5 min intervals to prevent thermal sensitization and behavioral disturbances using a commercially available apparatus (Ugo Basile Biological Research Apparatus) (Harregeaves et al., 1988). The von Frey filament stimulation experiments were conducted with calibrated nylon filaments (North Coast Medical) (see Figs. 1, 4) or with a Dynamic Aesthesiometer (Ugo Basile Biological Research Apparatus) (see Fig. 6). The threshold of response was calculated by using the up–down Excel program generously provided by the Basbaum Laboratory. Clear paw withdrawal, shaking, or licking was considered to be nociceptive-like response (Chaplan et al., 1994). In the cold-plate test (Columbus Instruments), the number of elevations of each hindpaw was recorded in the mice exposed to the cold plate (5 ± 0.5°C) during 5 min.

First experimental sequence, CB2−/− (16 males plus 16 females) and CB2+/+ (16 males plus 15 females) were used. In the second study, transgenic mice overexpressing CB2 receptors (12 males plus 12 females) and CB2+/+ (12 males plus 12 females) were used. Finally, CB2−/− (10 males), CB2+/+ (10 males), chimera-CB2 (12 males), and chimera-WT (10 males) mice were evaluated. Mice were first habituated for 1 h to each different experimental test once daily during 4 d. After the habituation period, baseline responses were established during 2 consecutive days for each paradigm in the following sequence: von Frey model, plantar test (30 min later), and cold-plate test (15 min later). All the behavioral tests were performed in the same group of animals. One day after baseline measurements, sciatic nerve injury was induced. A partial ligation of the sciatic nerve at mid thigh level just proximal to the trifurcation was performed with one 9-0 silk thread to induce neuropathic pain, as described previously (Malmberg and Basbaum, 1998). CB2−/− and CB2+/+ mice were tested in each paradigm on days 3, 6, 8, 10, and 15 after the surgical procedure using the same sequence as for baseline responses. Data were compared each experimental day by using a two-way ANOVA (surgery and genotype as between-group factors) followed by corresponding one-way ANOVA when appropriate.

Immunohistochemistry. At the end of the behavioral experiment, three to five mice per group were deeply anesthetized with ketamine/xylazine (50/10 mg/kg) and then intracardially perfused with heparinized phosphate buffer (PB), followed by 4% paraformaldehyde. The lumbar region...
of the spinal cord was removed, postfixed in 4% paraformaldehyde for 2 h, and cryopreserved in 15% sucrose solution at 4°C. The section from L2 to L6–S1 of the spinal cord was selected and then embedded in OCT, sliced in 25 μm sections on a cryostat, and mounted six sections per mice and two mice per slide in Star frost-coated slides.

The slides were incubated in polyclonal iba1 antibody (1:200; Wako Chemicals) for microglia staining or polyclonal GFAP antibody (1:1000; Dako) for astrocyte staining at 4°C overnight. The immunohistochemical assays were followed by incubation in the CY3 anti-rabbit secondary antibody (1:500; Jackson Immunoresearch) for iba1 or GFAP for 1 h at room temperature. After washing three times with 0.1 M PB, the slides were mounted with Mowiol.

For the low-magnification images, the stained sections of the lumbar dorsal horn were viewed at 10× objective and recorded with a Leica DMR microscope equipped with digital camera Leica DFC 300 FX.

Confocal images were obtained using a Leica SP2 confocal microscope, adapted to an inverted Leica DM IRBE microscope. Tissue sections of the lumbar dorsal horn were examined with a 40×, 1.25 numerical aperture oil-immersion Leica Plan Apochromatic objective. CY3 was excited with the 543 nm line of a green neon laser, and immunofluorescence images of three stained sections were taken for each animal. From each section, images were always recorded of the ipsilateral and contralateral dorsal horns. Nine to fifteen images were analyzed for each experimental group with ImageJ software measuring the percentage of stained occupied area. Data were compared by using one-way ANOVA and least significant difference post hoc analysis.

**CB2 staining.** The spinal cords were removed and frozen on dry ice without previous perfusion. They were sectioned in a cryostat at 20 μm thickness and mounted on glass slides. The tissues were fixed for 30 min in 4% formaldehyde dissolved in 0.1 M PBS, pH 7.3. Next, the slides were incubated for 15 min in 0.3% H2O2, for 60 min in 0.5% Triton X-100 and for 2 h in 3% BSA. The slides were washed in PBS at least two times for 5 min between each incubation phase. The sections were labeled at 4°C for 20 h using a rabbit polyclonal CB2 primary antibody (1:1000; Abcam), for microglia staining with iba1 polyclonal primary antibody (1:200; Wako Chemicals), for astrocyte staining with polyclonal GFAP primary antibody (1:1000; Dako), and for neuron staining with fluorescein-conjugated Neu-N (1:500; Millipore Bioscience Research Reagents) primary antibody. The double staining for CB2 receptors and for microglia or for astrocytes using secondary antibody from the same host was performed using the method of Toth and Mezey (2007). Briefly, after labeling the CB2 receptors, the process was followed by using a Tyramide Signal Amplification System (TSA Plus Fluorescence System; PerkinElmer Life and Analytical Sciences). The slides were incubated for 30 min in streptavidin-HRP (1:200) dissolved in TNB buffer (0.1 M Tris, pH 7.5, 0.15 M NaCl, 0.5% blocking reagent). The sections were washed three times for 5 min and incubated in fluorescein tyramide (1:100 in amplification reagent) for 6–9 min. The slides were washed in PBS (three times for 5 min), and fixed again for 15 min in 4% paraformaldehyde. After washing in PBS (three times for 10 min), the assay was followed by cooking the slides in the microwave in 10 mM citrate buffer, pH 6, for 5 min; after cooling (60–90 min), they were washed again. Next, the slides were incubated in 0.5% Triton X-100 and in PBS containing 1% bovine serum albumin and 10% goat serum for 60 min. The sections were labeled at 4°C for 20 h using rabbit polyclonal anti-GFAP primary antibody (1:1000; Dako) or rabbit polyclonal iba1 primary antibody (1:200; Wako Chemicals). The assay was followed by incubation in Cy3-conjugated donkey anti-rabbit IgG (1:250; Jackson Immunoresearch) secondary antibody. The assays were followed by incubation with FITC-conjugated donkey anti-rabbit (1:250; Jackson Immunoresearch) secondary antibody for microglia or for astrocytes at room temperature for 2 h. The sections were washed in water and mounted in Vectorshield Mounting Medium (Vector Laboratories; H-1200). The sections were viewed under fluorescence illumination (Zeiss Axiosplan microscope). The images were investigated using JVC (3-CCD) digital camera connected to the microscope with the help of NIS-Elements software (Nikon).

![Figure 1](image-url)  
**Figure 1.** Development of neuropathic pain is enhanced in male CB2−/− after sciatic nerve injury when compared with CB2+/- mice. A single tight ligature around one-third or one-half of sciatic nerve was made to induce the neuropathic pain in CB2−/− (n = 16) and CB2+/- mice (n = 16). Mice were tested in the ipsilateral and contralateral paw for evaluating mechanical allodynia (von Frey model; percentage of the basal CB2+/- sham-operated values) (A), thermal hyperalgesia (plantar test; withdrawal latency in seconds) (B), and cold allodynia (cold-plate test; number of paw elevations) (C) on days 3, 6, 8, 10, and 15 after surgery. The black stars represent comparison between sciatic nerve injury and sham-operated animals. The white stars represent comparison between genotypes. One star, p < 0.05; two stars, p < 0.01. Error bars indicate SEM.

**Results**

The manifestations of neuropathic pain are enhanced in CB2−/− mice

Hyperalgesia to a noxious thermal stimulus (plantar test), and allodynia to cold (cold-plate test) and mechanical stimuli (von Frey stimulation model) were first used as outcome behavioral measures of neuropathic pain. Baseline responses of CB2−/− mice and CB2+/- littermates were similar in the three nociceptive models, and sham operation did not produce any modification of these nociceptive thresholds in both genotypes. Sciatic nerve injury similarly enhanced thermal hyperalgesia and induced mechanical and thermal allodynia in the ipsilateral paw in both CB2−/− and CB2+/- mice (Fig. 1). Most strikingly, however, the same degree of thermal hyperalgesia and mechanical allodynia also developed in the contralateral paw of CB2−/− mice, revealing a mirror image of pain. This mirror image was not observed in CB2+/- mice (Fig. 1). A similar result was obtained in both sexes of CB2−/− and CB2+/- mice on the three nociceptive behavioral measures (supplemental Fig. 1, available at www.jneurosci.org as supplemental material). In agreement with previous reports (Ibrahim et al., 2006), a trend to enhance basal nociceptive response was observed in the plantar test in CB2−/− mice, although a significant effect (p < 0.05) was only revealed when analyzing data from both genders together.
Microglial cells are involved in the enhanced manifestations of neuropathic pain in CB2<sup>−/−</sup> mice

Glial cells are involved in neuropathic pain and express CB2 receptors after nerve injury (Ehrhart et al., 2005). Therefore, we have evaluated glial response in the dorsal horn of the lumbar spinal cord after sciatic nerve injury or sham operation in CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice to determine its possible involvement in the increased neuropathic pain sensitivity of CB2<sup>−/−</sup> animals. Sciatic nerve injury induced a similar enhancement of total microglial cell staining in the dorsal and ventral ipsilateral horn of the spinal cord in CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice. Interestingly, a similar microglial reaction was observed in the contralateral and ipsilateral horns in CB2<sup>−/−</sup> mice, but not in CB2<sup>+/+</sup> mice (Fig. 2). Similarly, an activation of microglia in the ipsilateral horns in CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice, and a stimulation in the contralateral horns only in CB2<sup>−/−</sup> mice were observed. In agreement with these findings, a significant increase of the staining for iba1, a specific marker for microglial cells, was observed in the ipsilateral side after nerve injury in CB2<sup>−/−</sup> mice and in the ipsilateral and contralateral side in CB2<sup>+/+</sup> mice. This increase was attributable to an enhancement in the number of microglial cells, which show specific morphological changes (Fig. 2B). Thus, typical resting microglia with a small cell body and thin and large ramifications were observed in sham-operated mice (Fig. 2B). After nerve injury, these resting microglia were present only in the contralateral side of CB2<sup>−/−</sup> mice. In contrast, the ipsilateral side of CB2<sup>+/+</sup> mice and both the ipsilateral and contralateral side of CB2<sup>−/−</sup> mice contained microglia with an activated phenotype. These cells have bigger cell bodies, as well as thicker and shorter ramifications (Fig. 2B). The same result was also found in astrocytic responses, with a similar activation in the ipsilateral horns in CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice, and a selective reaction in the contralateral horns only in CB2<sup>−/−</sup> mice (Fig. 2B). Thus, remarkably, the glial cell activation profile matched exactly the pattern of nociceptive hypersensitivity. Because glial activation and functional responses are inhibited by CB2 receptor stimulation (Ehrhart et al., 2005; Romero-Sandoval and Eisenach, 2007), these results suggest that the suppression of CB2 receptors had a disinhibitory effect on the glial response after sciatic nerve injury, thus leading to exacerbated pain response in these animals, which was mainly revealed in the contralateral side.

Figure 2. Enhanced glial activation in spinal cord of CB2<sup>−/−</sup> after sciatic nerve injury when compared with CB2<sup>+/+</sup> mice. A, Increase in iba1 (microglia) (n = 5) and GFAP (astrocyte) (n = 5) staining in dorsal horn of lumbar spinal cord after sciatic nerve injury in CB2<sup>−/−</sup> and in CB2<sup>+/+</sup> mice. White bars, Ipsilateral paw; black bars, contralateral paw. Iba-1 and GFAP visualized with CY3 anti-rabbit (red). Data are expressed as percentage of stained area. The black stars represent comparisons between sham-operated and nerve injury between ipsilateral and contralateral paw. The white stars represent comparisons between genotypes. One star, p < 0.05; two stars, p < 0.01. Error bars indicate SEM. B, Representative confocal images of the immunostaining of iba1 and GFAP recorded with 40× objective in lumbar dorsal horn of CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice. Iba-1 and GFAP visualized with CY3 anti-rabbit (red). C, Representative low-magnification images of iba1 and GFAP immunostaining recorded with 10× objective in the lumbar dorsal horn of sciatic nerve injury CB2<sup>−/−</sup> and CB2<sup>+/+</sup> mice.
Neuropathic pain is attenuated in transgenic mice overexpressing CB2 cannabinoid receptors

The manifestations of neuropathic pain induced by sciatic nerve injury were also evaluated in transgenic mice overexpressing CB2 cannabinoid receptors. These transgenic mice were generated by using a murine PrP promoter that is specifically expressed in neurons and glial cells (Castilla et al., 2005). We obtained five different transgenic lines. Three transgenic lines were selected by real-time PCR quantification. After being analyzed using the ΔCt method, data were normalized to GAPDH expression. The group with the lower value was assigned a value of 1. The stars represent differences in relative transcript abundance between endogenous and transgenic CB2 receptor (one-way repeated-measures ANOVA). Error bars indicate SEM.

Figure 3. CB2 expression and colocalization in male transgenic mice overexpressing CB2 receptors. A, Relative abundance of endogenous and transgenic CB2 RNA in PAG, thalamus, cervical spinal cord, and thoracic spinal cord of transgenic mice was determined by real-time PCR quantification. After being analyzed using the ΔCt method, data were normalized to GAPDH expression. The group with the lower value was assigned a value of 1. The stars represent differences in relative transcript abundance between endogenous and transgenic CB2 receptor (one-way repeated-measures ANOVA). Error bars indicate SEM. B, Negative immunostaining for CB2 receptor in the lumbar spinal cord of CB2<sup>−/−</sup> mice that serves as a control for CB2 staining in transgenic mice overexpressing CB2 receptors. C, Double-fluorescence immunostaining for CB2 receptor, GFAP (astrocyte), Neu-N (neuron), and iba-1 (microglia) in lumbar spinal cord sections from transgenic mice overexpressing CB2 receptors. First plot, Immunostaining for CB2 receptor (red; CY3 anti-rabbit) and for astrocyte marker GFAP (green; FITC anti-rabbit). Second plot, Same staining for CB2 receptor (red; CY3 anti-rabbit) and for neuron (fluorescein-conjugated Neu-N). Third plot, Same staining for CB2 receptor (red; CY3 anti-rabbit) and for microglial marker iba-1 (green; FITC anti-rabbit).

Sciatic nerve injury robustly enhanced the microglial response in the ipsilateral horn of the spinal cord in CB2<sup>−/+</sup> mice, indicated by a significant increase of iba1 staining (Fig. 5A,B). The enhanced iba1 staining was attributable to an increased number of microglia, with an activated phenotype. This response was significantly attenuated in transgenic mice overexpressing CB2 receptors. Microglial staining was not significantly modified in the contralateral horn in these groups of mice. Astrocytic staining was also significantly enhanced in the ipsilateral horn of the spinal cord in CB2<sup>−/+</sup> mice, but not in transgenic animals overexpressing CB2 receptors nor in the contralateral side in any experimental group (Fig. 5A,B).

Sciatic nerve injury in CB2<sup>−/+</sup>/CB2<sup>−/−</sup> bone marrow chimeric mice produced similar development of neuropathic pain as in CB2<sup>−/−</sup> mice

We have finally evaluated in vivo the involvement of the immune system in the responses observed in CB2<sup>−/−</sup> mice. For this pur-
percentage of the basal CB2 receptors. Development of neuropathic pain in male transgenic mice overexpressing CB2 receptors. Development of neuropathic pain in male transgenic mice overexpressing CB2 receptors (n = 12) and wild-type mice (n = 12). A single ligature around one-third or one-half of sciatic nerve was made to induce the neuropathic pain. Mice were tested in the ipsilateral and contralateral paw for evaluating mechanical allodynia (von Frey model; percentage of the basal CB2+/+ sham-operated values) (A), thermal hyperalgesia (plantar test; withdrawal latency in seconds) (B), and cold allodynia (cold-plate test; number of paw elevations) (C) on days 3, 6, 8, 10, and 15 after surgery. The black stars represent comparison between sciatic nerve injury and sham-operated animals. The white stars represent comparison between genotypes. One star, p < 0.05; two stars, p < 0.01. Error bars indicate SEM.

Discussion
The present results reveal a crucial role of the CB2 cannabinoid receptors in controlling the development of neuropathic pain through an immune mechanism linked to glial activation. Hyperalgesia and allodynia induced by sciatic nerve injury were enhanced in CB2−/− mice, as revealed by a mirror image of pain in the contralateral side. These behavioral manifestations of neuropathic pain matched the changes induced in microglial and astrocyte activation. In agreement, a reduced manifestation of neuropathic pain after nerve injury was observed in transgenic mice overexpressing CB2 receptors under the control of a PrP promoter in the brain and the spinal cord. Expression of transgenic CB2 receptors was pronounced in microglial cells and neurons, but absent in astrocytes, in agreement with the literature (Van Sickle et al., 2005; Romero-Sandoval et al., 2008). Decreased hyperalgesia, allodynia, and spinal glial activation in these transgenic mice could be related to the strong overexpression of CB2 receptors at the level of the spinal cord. However, these mice also showed an enhanced expression of CB2 receptors in supraspinal structures involved in pain transmission, such as the thalamus and the periaqueductal gray matter, which could also participate in the decreased manifestations of neuropathic pain. The opposite phenotype revealed in transgenic mice overexpressing CB2 receptors and CB2−/− mice underlines the relevance of these receptors in mediating the manifestations of neuropathic pain. Similar baseline responses were obtained in the different lines of genetically modified mice lacking or overexpressing CB2 receptors, indicating the absence of nociceptive changes under physiological conditions in these animals. These results suggest that the activation of CB2 receptors could attenuate the manifestations of neuropathic pain at lower doses than those required to induce antinociception.

The altered manifestations of neuropathic pain observed in CB2−/− mice and transgenic mice overexpressing CB2 receptors suggest that endocannabinoids play an important role in the control of pain under these pathological conditions. In support of this hypothesis, an enhancement in the levels of the two main endocannabinoids, anandamide and 2-arachidonoyl-glycerol, was revealed after sciatic nerve injury in the spinal cord and several brain areas involved in pain, such as the periaqueductal gray matter and the rostral ventral medulla (Petrosino et al., 2007). The endocannabinoid levels were also enhanced after sciatic nerve injury in the dorsal root ganglia (Mitirirattanakul et al., 2006) and the section of the sciatic nerve proximal to the lesion (Agarwal et al., 2007). These increased endocannabinoid levels are likely related to enhanced biosynthesis or decreased catabolism and transport because endocannabinoids are produced on demand without any substantial storage (Di Marzo, 1998). Therefore, endocannabinoids could produce a tonic activation of CB2 receptors after sciatic nerve injury that would limit the progression and manifestations of neuropathic pain. In agreement, both mechanical and thermal hyperalgesia produced after sciatic nerve injury were attenuated by the administration of N-arachidonoyl-serotonin, an inhibitor of fatty acid amide hydrolase, the enzyme responsible of the degradation of anandam-
CB2 receptors are present in microglial cells (Romero-Sandoval et al., 2008) and neurons (Van Sickle et al., 2005). However, the possible presence of CB2 receptors in neurons and its possible functional role is still a controversial issue that requires additional investigation. In the spinal cord, CB2 receptor expression is associated with the appearance of activated microglial cells after chronic pain produced by peripheral nerve injury (Zhang et al., 2003). Glial activation has proinflammatory actions (Watkins et al., 2003), and although it is not involved in acute pain (Raghavendra et al., 2003), its activation is required for the induction and development of chronic pain states (Raghavendra et al., 2003; Watkins et al., 2003). Thus, microglia activation is involved in the development of neuropathic pain through the release of several cytokines that are known to produce neuronal sensitization in the spinal cord (DeLeo and Yezierski, 2001; Clark et al., 2007) and initiate the neuroinflammatory process leading to the development of neuropathic pain (Watkins et al., 2001). The chemical modulators that activate microglial cells are under the control of immune mediators, as well as neuromodulators released by nearby neurons, such as prostaglandins (Tanga et al., 2006). IFN-γ (interferon-γ) is another mediator involved in microglia activation that can induce an upregulation of CB2 mRNA expression (Carlisle et al., 2002). The complete neuroinflammatory process leading to the progression of the neuropathic pain requires the coactivation of both microglia and astrocytes (Colburn et al., 1999). Cytokines that are released by the activated microglia, such as IL-1β (interleukin-1β), can be responsible for the subsequent activation of astrocytes, which permits the consolidation of the neuropathic pain state (John et al., 2004).

Interestingly, CB2 receptor stimulation has been reported to attenuate microglial activation (Ehrhart et al., 2005; Romero-Sandoval and Eisenach, 2007) and the release of cytokines by the activated microglia (Puffenbarger et al., 2000; Klegeris et al., 2003; Sheng et al., 2005). In agreement, CB2 agonists produce analgesic effects (Ibrahim et al., 2005; Beltramo et al., 2006) (for review, see Guindon and Hohmann, 2008) and reduce activated microglia in neuropathic pain models (Romero-Sandoval et al., 2008).

CB2 receptors located on microglial cells would play a crucial role in limiting the spreading of this neuroinflammatory process. Thus, the activity of CB2 receptors in microglial cells would reduce its activation during the development of neuropathic pain and the consequent release of proinflammatory cytokines. In the absence of CB2 receptors, a more widespread activation of microglial cells occurs after sciatic nerve injury, which would lead to an enhancement in the manifestations of neuropathic pain and to the presence of a mirror image of pain in the contralateral side.

An alteration of the central immune responses after nerve injury could be responsible for the enhanced manifestations of the neuropathic pain in CB2−/− mice. This hypothesis was demonstrated by replicating the enhanced behavioral and histological manifestations of neuropathic pain observed in CB2−/− mice in irradiated CB2+/+ mice transplanted with bone marrow cells.

Figure 5. Expression of glial activation in spinal cord of CB2−/− and transgenic mice overexpressing CB2 receptors. A, The increase of microglia and astrocytic response in dorsal horn of lumbar spinal cord after sciatic nerve injury is only observed in CB2−/− mice. Iba-1 staining (microglia) (n = 4 per group) and GFAP staining (astrocytes) (n = 4 per group) were visualized with CY3 anti-rabbit (red). Ipsilateral dorsal horns were represented with white bars, and contralateral dorsal horns were represented with black bars. Data are expressed as percentage of stained area. Error bars indicate SEM. The black stars represent comparisons between sham-operated and nerve injury or between ipsilateral and contralateral paw. One star, p < 0.05; two stars, p < 0.01. B, Representative confocal images of the immunostaining of Iba-1 (microglia) and GFAP (astrocyte) in lumbar dorsal horn of CB2−/− and transgenic mice overexpressing CB2 receptors recorded with the 40× objective.
from CB$_2$−/−. These CB$_2$−/− BM chimeric mice showed enhanced manifestations of neuropathic pain as revealed by allodynia, hyperalgesia, and astrocitic and microglial cell activation in the contralateral side of the spinal cord after sciatic nerve injury. By generating bone marrow-chimeric mice, we present evidence that newly recruited monocytes from the bone marrow of CB$_2$−/− deficient mice participate in the reconstitution of spinal cord microglia after peripheral nerve injury.

Recently, it has been demonstrated that bone marrow-derived cells that are recruited to the spinal cord are implicated in the development of neuropathic pain. In particular, CCR2 expression in either resident microglia or bone marrow-derived macrophages may be sufficient for the development of mechanical allodynia in a murine neuropathic pain model (Zhang et al., 2007). Subsequent to nerve injury, gradients formed by chemokine ligand 2 (CCL2) and CCL3 orchestrate the recruitment and activation of resident and monocyte-derived microglia via signaling through their respective receptors CCR2, CCR1, and CCR5 (Scholz and Woolf, 2007). CB$_2$ cannabinoid receptor activity may critically influence the induction of CCR2 expression by monocytes and thus inhibit their chemotaxis (Steffens et al., 2005). Moreover, endocannabinoids were found to abolish microglia activation by inhibiting NO (nitric oxide) release through a mechanism linked to the MAPK (mitogen-activated protein kinase) pathway (Eljaschewitsch et al., 2006). Therefore, our findings demonstrate a crucial role of the immune response mediated by microglia in the development of increased neuropathic pain sensitivity in the CB$_2$−/− animals. A direct action on peripheral CB$_2$ receptors located in primary afferent neurons (Wotherspoon et al., 2005; Beltramo et al., 2006) and in keratinocytes involved in the release of β-endorphins (Ibrahim et al., 2005) has been reported to be involved in the analgesic responses of CB$_2$ agonist. However, these peripheral effects of CB$_2$ receptors do not seem to be involved in the enhanced manifestations of neuropathic pain observed in the present study in CB$_2$ knock-out mice.

Mice genetically modified either by increasing or eliminating specific gene may be limited by the fact that this genetic change may be affecting not only the target gene but also other biological components, perhaps participating in the effects evaluated in these genetic models. Therefore, pharmacological studies using selective ligands of CB$_2$ receptors would be useful.
ful to confirm the relevance of the present results. Nevertheless, these genetic manipulations have been considered a key approach to the identification of alterations associated to different pathological conditions and to the discovering of new potential therapeutic targets in a variety of neuropsychiatric disorders. In this study, the use of different lines of genetically modified mice and the according results obtained in all these lines further support the relevance of the findings.

Our findings reveal a crucial role of the CB2 receptor in the modulation of the immune response of the nervous system during neuropathic pain. In contrast, the genetic disruption of the CB2 receptor had no major consequences on the development of neuropathic pain (Castañé et al., 2006) despite the high expression of these receptors in the CNS (Tsou et al., 1998). Only CB2 receptors expressed in peripheral nociceptors but not in the CNS seem to be involved in the manifestations of neuropathic pain (Agarwal et al., 2007). The selective involvement of CB2 receptors and the low expression in neurons (Van Sickle et al., 2005) further emphasize the relevance of these receptors in the central adaptive mechanisms leading to neuropathic pain. Therefore, CB2 cannabinoid agonists could represent a new group of pharmacological agents for the treatment of neuropathic pain devoid of any psychoactive side effects.
