**Nerve injuries often lead to neuropathic pain syndrome. The mechanisms contributing to this syndrome involve local inflammatory responses, activation of glia cells, and changes in the plasticity of neuronal nociceptive pathways. Cannabinoid CB$_2$ receptors contribute to the local containment of neuropathic pain by modulating glial activation in response to nerve injury. Thus, neuropathic pain spreads in mice lacking CB$_2$ receptors beyond the site of nerve injury. To further investigate the mechanisms leading to the enhanced manifestation of neuropathic pain, we have established expression profiles of spinal cord tissues from wild-type and CB$_2$-deficient mice after nerve injury. An enhanced interferon-γ (IFN-γ) response was revealed in the absence of CB$_2$ signaling. Immunofluorescence stainings demonstrated an IFN-γ production by astrocytes and neurons ipsilateral to the nerve injury in wild-type animals. In contrast, CB$_2$-deficient mice showed neuronal and astrocytic IFN-γ immunoreactivity also in the contralateral region, thus matching the pattern of nociceptive hypersensitivity in these animals. Experiments in BV-2 microglia cells revealed that transcriptional changes induced by IFN-γ in two key elements for neuropathic pain development, iNOS (inducible nitric oxide synthase) and CCR2, are modulated by CB$_2$ receptor signaling. The most direct support for a functional involvement of IFN-γ as a mediator of CB$_2$ signaling was obtained with a double knock-out mouse strain deficient in CB$_2$ receptors and IFN-γ. These animals no longer show the enhanced manifestations of neuropathic pain observed in CB$_2$ knock-outs. These data clearly demonstrate that the CB$_2$ receptor-mediated control of neuropathic pain is IFN-γ dependent.**

**Key words:** interferon-γ; CB$_2$ cannabinoid receptor; microglia; astrocytes; neuropathic pain; cytokine

Introduction

Neuropathic pain refers to pain or increased pain sensitivity caused by nerve injuries. There is now accumulating evidence that inflammatory processes at the site of the nerve injury, the dorsal root ganglia, and the spinal cord projection area contribute to the complex neuropathic pain pathology. Thus, nerve damage stimulates peripheral immune cells including neutrophil granulocytes, macrophages, mast cells, and T-lymphocytes followed by the activation of spinal cord microglia and astrocytes (Scholz and Woolf, 2007). The immune response is orchestrated by inflammatory mediators including cytokines, chemokines, ATP, neuropeptides, prostaglandins, and endocannabinoids (DeLeo and Yezierski, 2001; Clark et al., 2007). Endocannabinoid signaling through CB$_2$ receptors (Zhang et al., 2003) attenuates microglial activation and controls the regional restriction of the neuropathic pain (Ehrhart et al., 2005; Romero-Sandoval and Eisenach, 2007). On sciatic nerve ligation, mice lacking CB$_2$ receptors show an enhanced microglia response (Racz et al., 2008). Thus, activated microglia are found not only in the spinal cord region ipsilateral to the peripheral nerve injury as observed in wild-type controls, but rather throughout the spinal cord. The enhanced microglia response is accompanied by a more widespread neuropathic pain response with enhanced pain sensitivity in the ipsilateral and contralateral sites. Conversely, overexpression of CB$_2$ receptors in neurons and microglia resulted in a significant reduction of neuropathic pain responses. To further elucidate the cellular and molecular mechanism involved in the...
enhanced neuropathic pain response in the absence of CB2 receptor signaling, we have now established expression profiles from the affected spinal cord tissues. Our analysis provides strong evidence for an involvement of interferon-γ (IFN-γ) as a mediator of CB2 signaling in neuropathic pain.

### Materials and Methods

**Animal experimental conditions.** Animals were housed in groups of three to five and had *ad libitum* access to water and food. The housing conditions were maintained at 21 ± 1°C and 55 ± 10% relative humidity in a controlled light/dark cycle (light on between 8:00 A.M. and 8:00 P.M.). All experimental procedures and animal husbandry were conducted according to standard ethical guidelines (European Community Guidelines on the Care and Use of Laboratory Animals 86/609/EEC) and approved by the local ethical committee (Comité Ético Experimental Animal–Instituto Municipal de Asistencia Sanitaria/Universitat Pompeu Fabra, Bezirksregierung Köln). All experiments were performed under blind conditions.

**Behavioral experiments.** Hyperalgesia to noxious thermal stimulus (plantar test) and allodynia to mechanical stimuli (von Frey stimulation model) were used as outcome measures of neuropathic pain. In the plantar test, the mean paw withdrawal latencies for the ipsilateral and contralateral hindpaws were determined from the average of three separate trials, taken at 5 min intervals to prevent thermal sensitization and behavioral disturbances using a commercially available apparatus (Ugo Basile Biological Research Apparatus) (Hargreaves et al., 1988). The von Frey filament stimulation experiments were conducted with a Dynamic Aesthesiometer (Ugo Basile Biological Research Apparatus). Clear paw withdrawal, shaking, or licking was considered to be a nociceptive-like response (Chaplan et al., 1994).

IFN-γ−/− (eight males for nerve injury plus six males for sham) and double IFN-γ−/−/CB2−/− (seven males for nerve injury plus three males for sham) animals were used. Mice were first habituated for 1 h to each different experimental test once daily during 4 d. After the habituation period, baseline responses were established during 2 consecutive days for each paradigm in the following sequence: von Frey model and plantar test (30 min later). All the behavioral tests were performed in the same group of animals. One day after baseline measurements, sciatic nerve injury was induced. A partial ligation of the sciatic nerve at midthigh level just proximal to the trifurcation was performed with one thigh ligature using a 9-0 silk thread to induce neuropathic pain, as previously described (Malmberg and Basbaum, 1998). IFN-γ−/− and IFN-γ−/−/CB2−/− mice were tested in each paradigm on days 3, 6, 8, 10, and 15 and after the surgical procedure using the same sequence as used for baseline responses. Data were compared each experimental day by using a two-way ANOVA (surgery and genotype as between-group factors) followed by corresponding one-way ANOVA when appropriate.

**Microarray experiments.** Male and female CB2 knock-out (CB2−/−) mice and wild-type littermates (CB2+/-) on a C57BL/6J congenic background (Buckley et al., 2000) were used. At the end of the behavioral experiments (Racz et al., 2008), the mice were killed and the lumbar section of the spinal cords was rapidly dissected and fresh-frozen in liquid nitrogen. Tissue was stored at −80°C until RNA isolation. The samples were analyzed by MG_430 2.0 Affymetrix GeneChips in single array. Total RNA was extracted from spinal cord after mechanical homogenization using TRIzol (Invitrogen). mRNA was purified using RNeasy Mini kit (QIAGEN) according to the manufacturer’s instructions. The tissue samples from nine animals were pooled. Samples yielded −20 μg of total RNA. RNA integrity was assessed using Agilent Bioanalyzer 2100 (Agilent). Five micrograms of total RNA was converted into cDNA using StrataScript reverse transcriptase (Stratagene) according to the manufacturer’s instructions. Ten micrograms of all fragmented cDNA samples were hybridized to MG_430 2.0 Affymetrix GeneChips according to the manufacturer’s instructions. All samples reported a comparable number of genes expressed (58.1% in treated and 57.4% in the control groups). Microarray expression values were generated using MAS5 software “ArrayAssist 3.0” (Stratagene). The MAS5-obtained log2-transformed expression values were compared between tissues from sham-operated and sciatic nerve-ligated animals. A total of 490 transcripts were found to be differentially regulated by the nerve ligation at a level of p < 0.05. We further eliminated all transcripts that were upregulated or downregulated by more than twofold in two or more sham-operated tissues, and, furthermore, all those transcripts with absolute expression values <20. This selection yielded 219 transcripts for additional analysis.

**Bioinformatics analysis of the promoter regions of the differentially regulated genes reported in the microarray study.** Promoter regions spanning from −600 to +100 bp relative to the transcription start site were downloaded from public domain at University of California Santa Cruz (mouse genome assembly mm9). Duplicated RefSeq identifiers and overlapped regions were discarded to generate a nonredundant sequence dataset. Matches to putative regulatory motifs were obtained with 126 JASPAR transcription factor matrices at 0.90 similarity threshold (Sandelin et al., 2004). Motif overrepresentation was evaluated using 10,000 randomly sampled datasets of the same size taken from the rest of promoter sequences. Empirical p value as (r + 1)/(n − 1) was estimated from occurrences distribution for each specific matrix on randomly sampled datasets. In addition, random expectation (RE) was calculated from 100 datasets of 18,983 synthetic promoters. Each synthetic promoter sequence was generated using order-1 Markov chains from GpC, GC-rich or AT-rich regions obtained on nonredundant and nonoverlapping real promoters (Bellora et al., 2007). RE provides information on the noise of the motif prediction (a high number of hits usually indicates poor matrix quality) and on relative enrichment (observed/expected). A value of p < 0.01 was considered to be significant for all the analyses and motifs with enrichments <2X were excluded.

**Validation procedure.** Igtp, Tgtp, and Gbp2 mRNA were quantified by RT-PCR using gene expression assays (Applied Biosystems; Igtp, Mm00497611_m1; Tgtp, Mm00786826_s1; Gbp2, Mm00494575_m1). The real-time PCR amplifications were performed with the Taqman 7900HT from Applied Biosystems in 20 µl reaction volumes. Thermal cycling proceeded with one amplification cycle of denaturation at 95°C for 10 min, followed by 40 cycles of 95°C for 15 s and 60°C for 1 min.

### Figure 1. Classification of genes showing significant changes in expression in the spinal cord after sciatic nerve injury. About one-third of upregulated genes are responsible for the inflammatory/immunological processes, whereas only a small amount of genes belonging to this category was downregulated. A large number of genes involved in signaling and metabolism were upregulated and downregulated. A fewer number of genes regulating cell structure, translation/transcription, and DNA repair functions are in rather equal number upregulated or downregulated. A large number of genes with unknown function have a different expression after sciatic nerve injury.
Results were expressed as the relative amount of Igtgp, Tgtp, and Gbp2 normalized by β-actin expression. All reactions were performed in triplicate, and the data were analyzed with SDS analyzing software (Applied Biosystems; SDS 2.2.2) as described previously (Livak and Schmittgen, 2001). Double immunofluorescence staining. Five mice per group were anesthetized with ketamine/xylac (50/10 mg/kg) and then intracardially perfused with heparinized phosphate buffer, followed by 4% paraformaldehyde. The lumbar region of the spinal cord was removed and cryopreserved in 30% sucrose solution at 4°C. The section from L2 to L6–S1 of the spinal cord was selected and then embedded in OCT, sliced in 25 μm sections on a cryostat, and six sections per mice and two mice per slide mounted in Star frost-coated slides. The slides were incubated in anti iba-1 antibody (1:200; Wako Chemicals) for microglia staining or polyclonal GFAP antibody (1:1000; Dako) for astrocyte staining and monoclonal anti-IFN-γ antibody (1:150; Mil-

Results
Transcriptional changes induced by peripheral nerve injury
To evaluate transcriptional events at the level of the spinal cord that may underlie the increased pain sensitivity after nerve injury and the enhanced neuropathic pain phenotype of CB2−/− animals, we performed a series of microarray experiments in CB2−/− and CB2+/+. For this purpose, we dissected lumbar spinal cord segments ipsilateral and contralateral to the nerve ligation from CB2−/− and CB2+/+ mice, plus the corresponding sham controls. RNA from these tissues was isolated and analyzed on Affymetrix GeneChip arrays (MG_430 2.0).

We found 490 genes differentially expressed in tissues from animals with nerve injury compared with sham control. Of these transcripts, we excluded from additional analysis all those with expression levels <0.5% of β-actin and those showing differential expression (more than log 1) in more than one of the sham control tissues. We thus obtained a total of 219 transcripts, of which 117 were downregulated and 102 upregulated (supplemental Table S1, available at www.jneurosci.org as supplemental material). These transcripts included a large number of genes with a function in cell signaling, regulation of gene expression

Figure 3. Expression of genes regulated by IFN-γ or IFN-α after partial sciatic nerve ligation (PNL) was upregulated. A. The increase in expression level of IFN-γ-regulated genes was more intensive in CB2−/− than in CB2+/+ mice, whereas the upregulation in IFN-α-regulated genes was less intensive in CB2−/− animals. B. Taqman real-time PCR analysis of the expression of three GTPase regulated genes also showed a stronger expression change in CB2−/− than in CB2+/+ mice after neuropathy. wt-i, Ipsilateral paw of CB2+/+ mice; wt-c, contralateral paw of CB2+/+ mice; ko-i, ipsilateral paw of CB2−/− mice; ko-c, contralateral paw of CB2−/− mice.
and immune responses (Fig. 1), which is consistent with the observed microglia response triggered by the nerve injury (Racz et al., 2008). Most of the suppressed, 93, and one-half, 47, of the induced transcripts were more strongly regulated on the ipsilateral compared with the contralateral side (supplemental Table 1, available at www.jneurosci.org as supplemental material).

We considered those transcripts that were more strongly induced or repressed in CB2−/− animals, or vice versa, as potential candidate mediators of the enhanced neuropathic pain phenotype. Indeed, 54 transcripts were more strongly regulated in CB2−/− mice and 36 in CB2+/+ mice (Fig. 2).

**Enhanced upregulation of interferon-γ-inducible transcripts in CB2 knock-out mice**

We next performed a bioinformatics analysis to obtain the candidate cis-regulatory motifs and their binding transcription factors in a given dataset of coregulated genes. This method was specifically developed to identify regulatory motifs that are highly specific for a group of genes under study (N. Bellora and M. Alba, unpublished data). In this analysis, we used 72 promoter regions of the genes differentially regulated after nerve injury in both genotypes, as revealed by microarray experiments (supplemental Table 1, available at www.jneurosci.org as supplemental material). We identified a significant overrepresentation of transcription factor interferon regulatory factor-1 (IRF-1) and IRF-2 binding sites (p < 0.0001) in 22.2 and 6.9% of the genes analyzed, respectively, thus indicating a high enrichment over synthetic sequences and random promoter datasets (Table 1).

These data indicate a strong interferon response after nerve injury. Interestingly, a number of IFN-γ-induced genes were among those transcripts that were more strongly regulated in the absence of CB2 receptors (Fig. 3A). These transcripts included several members of the 47 kDa and 65 kDa families of GTPases. In CB2+/+ animals, we observed a 1.7- to 2.4-fold upregulation, with the exception of Tgtp, which was 3.6 times higher, whereas these transcripts were 2.3- to 7-fold upregulated in CB2−/− mice. Validation of three of these genes using Taqman real-time PCR analysis confirmed their stronger induction in CB2−/− animals (Fig. 3B). IFN-inducible GTPases such as Igtp and Gbp2 have been implicated in the regulation of immune responses toward infections (Martens and Howard, 2006; Degrandi et al., 2007). These results suggest an enhanced IFN-γ response in CB2−/− mice after nerve injury.

The enhanced manifestations of neuropathic pain were not observed in double IFN-γ−/−/CB2−/− mice

To clarify the involvement of interferon proteins in the enhanced manifestations of neuropathic pain in CB2−/− mice, we crossed CB2−/− animals to IFN-γ−/− mice to generate double knock-out mice deficient in both CB2 receptors and IFN-γ. These double knock-out animals showed no gross behavioral phenotypes or any obvious symptoms of a disease.

We therefore subjected these mice to a peripheral nerve ligation and evaluated hyperalgesia to a noxious thermal stimulus (plantar test), and allodynia to a mechanical stimulus (von Frey stimulation model) as outcome behavioral measures of neuropathic pain at various time points after the nerve injury. Baseline nociceptive responses of IFN-γ−/− and double IFN-γ−/−/CB2−/− mice were similar in the plantar test and von Frey stimulation model. Sham operation also did not produce any modification of these nociceptive thresholds in both genotypes. Furthermore, thermal hyperalgesia and mechanical allodynia induced by sciatic nerve injury in the ipsilateral paw were similar in IFN-γ−/− and double IFN-γ−/−/CB2−/− mice (Fig. 4) and no mirror image of pain was revealed in any experimental group. Thus, the enhanced manifestations of neuropathic pain in CB2−/− mice was completely suppressed in the absence of IFN-γ. Therefore, IFN-γ is directly involved in the regulation of neuropathic pain responses by CB2 receptors.

**Immunofluorescence analysis of IFN-γ expression in microglial cells and astrocytes**

To further study IFN-γ in activated microglia and astrocytes under these experimental conditions, double immunofluorescence analysis was performed using antibodies against iba-1 or GFAP and IFN-γ in CB2−/− and wild type mice exposed to sciatic nerve injury. IFN-γ signals were detected in the dorsal horn of lumbar spinal cord mainly in the ipsilateral side of CB2−/− mice, as well as in the ipsilateral and contralateral sides of CB2−/− mice. IFN-γ immunoreactivity could be detected in a minor subset of GFAP+ astrocytes but did not colocalize with iba+ microglial cells. Using the intensity correlation analysis, we observe that the colocalization of IFN-γ signal with the GFAP signal was significantly enhanced in the ipsilateral and contralateral dorsal horns of the CB2−/− mice, whereas in CB2+/+ this effect was only revealed in the ipsilateral dorsal horn. The expression of IFN-γ in astrocytes matched the pattern of nociceptive hypersensitivity (see Fig. 6).

IFN-γ protein has also been reported to be expressed in neurons (Neumann et al., 1997). Indeed, a positive IFN-γ staining was observed in the cytoplasm of cells recognized as neurons by their morphology (Fig. 5) identifying spinal cord neurons as a potential source for IFN-γ after nerve injury.
Role of the CB2 receptor in IFN-γ-inducible inducible nitric oxide synthase mRNA and CCR2 mRNA expression in microglial cells

Peripheral nerve injury induced inflammation is associated with enhanced gene transcription of inducible nitric oxide synthase (iNOS) and nitric oxide (NO) release from locally recruited macrophages and microglial cells (Martucci et al., 2008). Recent studies demonstrated that spinal microglial infiltration in neuropathic pain is critically dependent on binding of chemokine (iNOS) and nitric oxide (NO) release from locally recruited microglial cells (Zhang et al., 2007). To test the hypothesis that IFN-γ-inducible iNOS and CCR2 gene expression is influenced by CB2 signaling in microglial cells, we stimulated BV-2 microglial cells with IFN-γ in the presence or absence of the CB2 agonist (6aR,10aR)-3-(1,1-dimethylbutyl)-6a,7,10,10a-tetrahydro-6,6,9-trimethyl-6H-dibenzo[b,d]pyran (JWH-133) (Fig. 7). mRNA expression of CB2 is upregulated in IFN-γ-stimulated BV-2 cells and unaffected by treatment with JWH-133 and the CB2-selective antagonist N-[1-(15)-endo-1,3,3-trimethylbicyclo[2.2.1]heptan-2-yl]-5-(4-chloro-3-methylphenyl)-1-(4-methylbenzyl)-pyrazole-3-carboxamide (SR144528) (SR2). However, exposure of IFN-γ-stimulated microglial cells to JWH-133 inhibited iNOS gene expression, whereas the CB2 antagonist SR144528 was able to reverse this effect (Fig. 7). This demonstrates that this inhibitory effect of the JWH-133 is indeed mediated by the CB2 receptors. Next, we tested the influence of CB2 receptor signaling on CCR2 mRNA expression in BV-2 microglial cells after stimulation with IFN-γ. Treatment of BV-2 cells with JWH-133 significantly diminishes IFN-γ dependent CCR2 mRNA upregulation in BV-2 cells. This inhibitory effect was fully reversed in the presence of the CB2 antagonist SR144528. These findings suggest that CB2 signaling significantly downregulates IFN-γ-dependent iNOS and CCR2 gene expression in microglial cells, the gene products of which are critically involved in activation and chemotaxis of microglial cells after peripheral nerve injury.

Discussion

The present results revealed the crucial role of CB2 cannabinoid receptors in the development of neuropathic pain through an immune mechanism linked to modified IFN-γ activity. Hyperalgesia and allodynia induced by sciatic nerve injury were enhanced in CB2−/− mice, as revealed by a mirror image of pain in the contralateral side. These behavioral manifestations of neuropathic pain matched the changes induced in microglial and astrocyte activation, astrocytic IFN-γ expression, and other biochemical parameters related to the immune response.

Glial activators include chemokines that enhance pain sensation and are under the control of immune mediators, as well as several neuromodulators released by nearby neurons, such as prostaglandins (Tanga et al., 2006). Interferons represent crucial modulators of the central and peripheral immune responses (Bach et al., 1997) and the enhanced induction of IFN-γ genes in CB2−/− mice could participate in their nociceptive hypersensitivity. Indeed, a prolonged spinal increase in IFN-γ levels in inflammatory responses in diseases such as viral infections and...
multiple sclerosis, is thought to contribute to the associated persistent pain states (Miyazaki et al., 2008). Furthermore, IFN-γ treatments in cancer therapy can result in spontaneous pain in humans (Quesada et al., 1986; Mahmoud et al., 1992). Intrathecal IFN-γ administration in mice can also cause pain-related behaviors in normal, but not in IFN-γ receptor knock-out mice (Robertson et al., 1997). Although the molecular and cellular mechanism of interferon-induced pain remains mostly unclear, it has been demonstrated that IFN-γ can cause spontaneous firing of dorsal horn neurons in vitro and in vivo, as well as enhanced wind-up responses to electrical stimulation (Vikman et al., 2003, 2005, 2007). Interestingly, the pharmacological activation of CB2 cannabinoid receptors suppresses wind-up responses of spinal nociceptive neurons and this effect was more pronounced in the presence of pathological pain (Nackley et al., 2004).

The enhanced IFN-γ response revealed by microarray experiments in CB2−/− mice exposed to nerve injury has an important functional relevance in vivo. Thus, a direct relationship between the enhanced IFN-γ response and the neuropathic pain manifestations of CB2−/− mice was demonstrated by using double knock-out animals deficient in CB2 receptors and IFN-γ. The behavioral phenotype of CB2−/− mice showing an enhanced neuropathic pain was completely abolished in these double knock-out animals. IFN-γ is a crucial modulator of the central and peripheral immune responses suggesting that an immune alteration seems to underlie the neuropathic pain responses in CB2−/− mice.

The manifestations of neuropathic pain observed in CB2−/− mice and double knock-out mice deficient in CB2 and IFN-γ suggest that endocannabinoids play an important role in the control of the immune responses leading to the development of neuropathic pain. In support of this hypothesis, an enhancement in the levels of the two main endocannabinoids, anandamide and 2-arachidonoyl-glycerol, was revealed after sciatic nerve injury in the spinal cord and several brain areas involved in pain, such as the periaqueductal gray matter and the rostral ventral medulla (Petrosino et al., 2007). The endocannabinoid levels were also enhanced after sciatic nerve injury in the dorsal root ganglia (Mitirirattanakul et al., 2006) and the section of the sciatic nerve proximal to the lesion (Agarwal et al., 2007). These increased endocannabinoid levels are likely related to enhanced biosynthesis or decreased catabolism and transport because endocannabinoids are produced on demand without any substantial storage (Di Marzo, 1998).

Therefore, endocannabinoids could produce a tonic activation of CB2 receptors after sciatic nerve injury that would limit the immune responses leading to the development of neuropathic pain. In agreement, both mechanical and thermal hyperalgesia produced after sciatic nerve injury were attenuated by the administration of N-arachidonoyl-serotonin, an inhibitor of fatty acid
agreement, pharmacological activation of CB1 receptors have manifestations of neuropathic pain (Agarwal et al., 2007). In eral nociceptors but not in the CNS seem to be involved in the (Eljaschewitsch et al., 2006). Our data revealed that IFN- linked to the MAPK (mitogen-activated protein kinase) pathway croglia activation by inhibiting NO release through a mechanism 2005). Moreover, endocannabinoids were found to abolish mi- sequences on the development of neuropathic pain (Castan˜e´ et al., (Tsou et al., 1998). However, CB1 receptors expressed in periph- of endocannabinoids in the modulation of neuropathic pain. anandamide (Maione et al., 2007), which further support the role 3500 M). cDNA was generated from BV-2 cells and expression of CB2 , iNOS, and CCR2 mRNA was evaluated by real-time RT-PCR. Figure 7. The CB2 agonist JWH-133 reduces IFN-γ-inducible iNOS and CCR2 mRNA expression in microglial cells. Relative expression levels of CB2, iNOS, and CCR2 mRNA were determined by quantitative real-time PCR. BV-2 microglial cells were stimulated either with 50 U/ml IFN-γ for 15 h alone, or in the presence of JWH-133 (5 μM) with or without CB2 receptor antagonist SR144528 (1 μM). cDNA was generated from BV-2 cells and expression of CB2, iNOS, and CCR2 mRNA was evaluated by real-time RT-PCR. Quantitative RT-PCR results are expressed as a ratio of average copies per copy of GAPDH for mean values ± SEM of n = 6 for all conditions. *p < 0.05; **p < 0.005 (BV-2 cells stimulated with IFN-γ-ys vs with IFN-γ in the presence of 5 μM JWH-133).

amide hydrolase, the enzyme responsible for the degradation of anandamide (Maione et al., 2007), which further support the role of endocannabinoids in the modulation of neuropathic pain.

In contrast with the results here obtained in CB2−/− mice, the genetic disruption of the CB1 receptor had no major consequences on the development of neuropathic pain (Castan˜e´ et al., 2006) despite the high expression of these receptors in the CNS (Tsou et al., 1998). However, CB2 receptors expressed in peripheral nociceptors but not in the CNS seem to be involved in the manifestations of neuropathic pain (Agarwal et al., 2007). In agreement, pharmacological activation of CB1 receptors have also been reported to reduce pain sensitivity in a variety of neuropathic pain models (Pertwee, 2005).

Subsequent to nerve injury, gradients formed by CCL2 and CCL3 orchestrate the recruitment and activation of resident and monocyte-derived microglia via signaling through their respective receptors CCR2, CCR1, and CCR5 (Scholz and Woolf, 2007). In particular, CCR2 expression in either resident microglia or bone marrow-derived macrophages may be sufficient for the development of mechanical allodynia in a murine neuropathic pain model (Zhang et al., 2007). CB2 cannabinoid receptor activity may critically influence the induction of CCR2 expression by monocytes and thus inhibit their chemotaxis (Steffens et al., 2005). Moreover, endocannabinoids were found to abolish microglia activation by inhibiting NO release through a mechanism linked to the MAPK (mitogen-activated protein kinase) pathway (Eljaschewitsch et al., 2006). Our data revealed that IFN-γ treatment of mouse BV-2 microglial cells evoked marked microglial activation as indicated by induction of iNOS and CCR2 gene expression. CB2 signaling, however, interfered with the expression of these two IFN-γ-inducible genes in BV-2 cells. These data suggest that CB2 receptor signaling exerts antiinflammatory effects in the neuropathic response by controlling IFN-γ-mediated microglial activation and recruitment. Therefore, these data complement our in vivo observations in the neuropathic response in CB2−/− mice.

Mice genetically modified either by increasing or eliminating specific gene may be limited by the fact that this genetic change may be affecting not only the target gene but also other biological components, perhaps participating in the effects evaluated in these genetic models. Therefore, pharmacological studies using selective ligands of CB2 receptors would be useful to confirm the relevance of the present results. Nevertheless, these genetic manipulations have been considered a key approach to the identification of alterations associated to different pathological conditions and to the discovering of new potential therapeutic targets in a variety of neuropsychiatric disorders. In this study, the according results obtained in CB2−/− mice and double knock-out mice deficient in CB2 and IFN-γ together with the pharmacological studies performed in vitro further support the relevance of the findings.

Our immunofluorescence analysis revealed that IFN-γ was mainly expressed in neurons after sciatic nerve injury and this expression of IFN-γ matched the pattern of nociceptive hyper- sensitvity in all experiments. IFN-γ expression was also present in astrocytes, but absent in microglia. Previous studies have reported the presence of CB2 receptors in microglial cells (Romero-Sandoval et al., 2008) and neurons (Van Sickle et al., 2005). However, the possible presence of CB2 receptors in neurons and its possible functional role is still a controversial issue that requires additional investigation. Taken all these data into consideration, we can postulate a mechanism to explain the modulation of neuropathic pain through CB2 receptor activation (Fig. 8). Thus, the neuroinflammatory process leading to the development of neuropathic pain seems to be initiated by the microglial activation produced after nerve injury (Scholz and Woolf, 2007). This process requires a coactivation of astrocytes, which, together with neurons, release IFN-γ and promote consolidation and progression of the neuropathic pain state (Zhang et al., 2007). IFN-γ promotes microglia activation by the induction of several inflammatory pathways, including an enhancement in iNOS and CCR2 activity. Interestingly, previous studies have reported the expression of IFN-γ receptors in microglial cells and its modulation under pathological conditions (Cannella and Raine, 2004). CB2 receptors on microglial cells would play a crucial role to control and limit the spreading of this neuroinflammatory process. Thus, the activity of CB2 receptors in microglial cells would reduce the activation of these cells during neuropathic pain by regulating the expression of iNOS and CCR2. In the absence of CB2 receptors, IFN-γ would produce a more widespread activation of microglial cells, which would enhance the manifestations of neuropathic pain and would be responsible for the presence of a mirror image of pain in the contralateral side.
