ABSTRACT

Although the efficacy of omalizumab in the treatment of Chronic Spontaneous Urticaria (CSU) has been clearly demonstrated, its mechanism of action that results in improvement of CSU symptoms is not entirely understood. This study investigated the effect of omalizumab on the high-affinity IgE receptor (FcεRI) expression on blood basophils from patients with active CSU, and its association with the clinical response. Patients exhibiting significant clinical improvement showed a sharp reduction of the levels of basophil FcεRI after 4 weeks that was maintained throughout the total duration of the treatment. Such evolution was not observed in non-responder patients. Furthermore, non-responders showed significantly lower baseline FcεRI levels than responders. Baseline basophil FcεRI expression was found to be a potential immunological predictor of response to omalizumab (100% sensitivity and 73.2% specificity). The results shown in this study contribute to understand the therapeutic benefit and mechanism of action of anti-IgE therapy in CSU.

Keywords: Basophils, down-regulation, FcεRI, IgE receptor, omalizumab
INTRODUCTION

Chronic spontaneous urticaria (CSU) represents the most common subtype of chronic urticaria and is defined as the appearance of evanescent wheals, angioedema or both that occurs suddenly and persists for longer than 6 weeks (1). Although CSU is usually not a life-threatening condition, its symptoms (cutaneous swelling, itch and pain) may have a profound impact on various aspects of patients’ everyday life (1).

Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that specifically binds circulating IgE preventing its attachment to the high affinity IgE receptor (FcεRI) of immune cells such as basophils and mast cells (2–4). It was originally approved for the treatment of moderate-to-severe persistent allergic asthma (5,6), and later in 2014, for the treatment of CSU (5,7). Several randomized clinical trials have confirmed its efficacy and safety for the treatment of CSU, showing significant reductions in the signs and symptoms of the disease compared to placebo (8–10). It also constitutes the first drug approved for patients with CSU who remain symptomatic despite H1-antihistamine treatment. Nonetheless, approximately 41-48% of patients seen in clinical trials (8–10) and 17-23% in the real-world clinical setting (11–13) do not exhibit a complete or significant response to omalizumab therapy. Given this response rate and the expense associated with its use, the identification of biomarkers predicting responsiveness to this treatment in CSU would prove valuable in routine clinical practice.

Furthermore, the mechanisms by which omalizumab might achieve its therapeutic effects on patients with CSU are not completely understood (4,14). In allergic rhinitis and asthma it has been showed that omalizumab has the ability to reduce free IgE serum levels and consequently down-regulate FcεRI receptors on basophils, thereby preventing the release
of inflammatory mediators that cause allergic signs and symptoms (2,3,15–17). However, to our knowledge, this mechanism of action has not been assessed in CSU. Hence, we sought to investigate the effect of omalizumab on basophil expression of FcεRI receptor in a cohort of patients with active CSU, and its possible association with the clinical response. Moreover, we evaluated the basophil FcεRI receptor expression as a potential predictor of response to omalizumab therapy.

PATIENTS AND METHODS

Subjects and study design
Consecutive adult patients controlled at the Urticaria Clinic of the Department of Dermatology of Hospital del Mar (Barcelona) with moderate-to-severe persistent and active CSU (7-days Urticaria Activity Score [UAS7] ≥16 (1)) and refractory to antihistamine therapy were included in the study during the period comprised from January 2014 to December 2015. Following a systematized prospective protocol, treatment with omalizumab 300 mg was administered every 4 weeks. Peripheral blood samples were obtained form these patients prior to the 1st (baseline), 2nd, 3rd, 6th and 12th injections. Exclusion criteria for study participation included < 18 years of age, concomitant treatment with oral corticosteroids and/or other immunosuppressive agents and suffering from a chronic pruritic disease besides CSU (in order to avoid potential interferences on evaluated clinical scores). Additionally, peripheral blood samples from a control group of healthy adult volunteers without family and personal history of allergic asthma, allergic rhinitis, chronic urticaria and atopic dermatitis were also evaluated. The local Clinical Research Ethics Committee granted ethical approval for the study (approval no. 2012/4913/I).

Clinical variables
Clinical variables were evaluated using the following patient-reported outcomes (PROs) (1,18,19): Urticaria Activity Score (UAS; UAS7 is a composite score of itch severity and hive count over 7 days; range 0-42) and Urticaria Control Test (UCT, a validated tool for assessing disease control in routine clinical practice; range 0-16). Response to therapy was assessed at 6 month of treatment and was defined as an improvement of the patients’ signs and symptoms achieving UAS7 ≤6 or ≥90% of reduction in the UAS7 (1,20,21).

Basophil cell preparation and flow cytometry
Two independent researchers evaluated the levels of basophil FcεRI receptor and the PROs. FcεRI receptor expression on basophils was measured by flow cytometry from peripheral blood samples obtained from CSU patients on day 0 and on weeks 4, 8, 20 and 44 of treatment, and from Healthy Controls (HCs). Flow cytometry analysis was performed following standard procedures. Briefly, 150μl of anticoagulated blood was incubated on the same day of collection during 20 minutes at 4 ºC with an excess of human immunoglobulins to block unspecific binding. Afterwards, blood was stained with either anti-CD123-PE (BD) or anti-CD193-APC (Miltenyi) to identify basophils and with anti-FcεR1a-FITC (clone CRA1, Ebiosciences) or an isotype control to establish the expression of FcεRI on the surface of blood basophils. After incubation, red blood cells were lysed with a hypotonic solution and samples were analysed by flow cytometry using the FACSDiva software. At least 2x10^5 events were acquired. Gating strategy is represented in Figure 1. Levels of basophil FcεRI receptor are expressed in MFI (Mean Fluorescence Intensity).

Statistical analysis
All analyses were carried out with the SPSS 21.0 statistical package. Descriptive statistics
were performed for each variable, using median, percentiles 25\textsuperscript{th} (P25) and 75\textsuperscript{th} (P75) for quantitative variables, and absolute (n) and relative (%) frequencies for categorical variables. Chi-square test and Mann-Whitney $U$ test were used to compare the demographic characteristics and the baseline FceRI receptor expression between patients with CSU and HCs. Pearson’s correlation was used to evaluate the association of the FceRI receptor expression with serum IgE levels and blood basophil count. Friedman test was used to detect differences over time in the FceRI receptor expression, UAS7 and UCT during omalizumab therapy. Post-hoc comparisons were performed using Wilcoxon test, and $p$-values were adjusted using the Bonferroni correction. A mixed linear model was applied to compare the FceRI receptor expression between responder and non-responder patients (subjects as random effects, weeks of treatment as fixed effects). A receiver-operating characteristic (ROC) curve analysis was used to evaluate the baseline FceRI receptor expression as a potential predictor of response to omalizumab therapy. A $p$-value <0.05 was considered statistically significant.

**RESULTS**

**Demographics**

A total of 91 subjects, 47 patients with active CSU and 44 HCs, were enrolled in this single-centre study. In the control group, the median (P25-P75) age was 45 (33-59) years, and 34 out of 44 (77.3\%) were women. Demographic and clinical features of CSU group are summarised in Table I. The median (P25-P75) age in this population was 51 (41-64) years and there were 37 (78.7\%) women and 10 (21.3\%) men. After 6 months of treatment, 38 out of 47 (80.9\%) patients with CSU achieved significant clinical improvement and were classified as “responders” (median value of UAS7 and UCT at 6 months: 0 and 14, respectively), and the remaining 9 (19.1\%) as “non-responders” (median value of UAS7
and UCT at 6 months: 23 and 2, respectively). Despite responder patients presented higher total IgE levels at baseline ($p= 0.0003$) and a lower rate of positive autologous serum skin test ($p= 0.022$), both groups showed the typical features of “classic” CSU (Table I). At 12 months of treatment, responder patients showed a satisfactory continued clinical response (median value of UAS7 and UCT at 12 months: 2 and 13, respectively), whereas non-responders did not exhibit significant improvement of CSU symptoms (median value of UAS7 and UCT at 12 months: 26 and 6, respectively).

Baseline FceRI receptor expression in CSU patients and HCs

The median (P25-P75) expression of the basophil FceRI receptor at baseline was significantly higher in patients with CSU compared to the HCs group (11430 [7600-16259] and 4743 [2770-7406] of MFI, respectively) ($p< 0.0001$) (Fig. 2a). However, the median [P25-P75] expression at baseline in non-responder patients (577 [493-705] of MFI) was significantly lower than in responders (12227 [10130-17899] of MFI; $p< 0.0001$) and in HCs ($p< 0.0001$) (Fig. 2b).

Effect of omalizumab on basophil FceRI receptor expression

The evolution of the basophil FceRI receptor expression, UAS7 and UCT values during the 12 months of treatment of the 47 patients with CSU is shown in Figure S1. Overall, a significant sharp drop in the basophil FceRI receptor expression was observed after the first dose of omalizumab (median [P25-P75] reduction from baseline at 4 weeks: 88.1% [80.9- 90.7]; $p< 0.0001$) (Fig. S1a). This trend was maintained throughout the whole treatment (median reduction from baseline at weeks 8, 20 and 44: 91.0% in all cases). A similar evolution was observed for the values of UAS7 (median reduction from baseline at weeks 4, 8, 20 and 44: 90.6%, 87.4%, 88.2% and 91.4%, respectively) and UCT (median
increase from baseline at weeks 4, 8, 20 and 44: 78.6%, 78.5%, 77.5% and 75.0%, respectively) (Fig. S1b). A significant association was found between such a reduction in the FcεRI receptor expression and the clinical improvement observed during the therapy ($p<0.0001$).

The kinetic of omalizumab-induced reduction in the FcεRI receptor expression on blood basophils in responder and non-responder patients is shown in Figure 3a. This kinetic was significantly different between these two subgroups, with a lower reduction in non-responders at all time points (median reduction from baseline at weeks 4, 8, 20 and 44: 57.4% vs. 89.2%; 35.3% vs. 91.9%; 35.7% vs. 92.2%; 11.9% vs. 91.8%; respectively) ($p<0.0001$). Furthermore, a different evolution was also observed for the values of UAS7 ($p<0.0001$) and UCT ($p<0.0001$) between responders and non-responders (Fig. 3b-c), which were consistent with the aforementioned evolution of FcεRI receptor levels.

**Baseline FcεRI receptor expression as a predictor of response to omalizumab therapy**

The distribution of the baseline FcεRI receptor expression in responder and non-responder patients compared to the median value of the control group (i.e. 4743 of MFI) is shown in Figure 4. The baseline expression was found to be below this value in the 9 non-responders, and above in the 38 responders. In view of these results, we sought to evaluate the baseline FcεRI receptor expression on basophils as a potential predictor of the response to omalizumab therapy, and the median value of the control group presented a 100.0% of sensitivity (i.e. proportion of non-responders correctly identified) and a 73.2% of specificity (i.e. proportion of responders correctly identified) to predict the therapeutic response (area under the ROC curve: 0.967; $p<0.001$).
FcεRI receptor expression, serum IgE levels and blood basophil count

Finally, we investigated if basophil FcεRI receptor expression could be associated with total serum IgE levels and/or blood basophil count, all of them assessed at baseline. A positive correlation was found between IgE levels (median [P25-P75]: 116 [42-277] kU/L) and the FcεRI receptor expression (R= 0.573; p< 0.001). Conversely, no association was detected between blood basophil count (median [P25-P75]: 0.032 [0.015- 0.065] x10^3/μL) and the FcεRI receptor expression (R= 0.199; p= 0.18).

DISCUSSION

Omalizumab is a monoclonal antibody that selectively binds to human IgE on its Fc domain (5). By this binding, the interaction between IgE and its high (FcεRI) and low (CD23) affinity receptor is blocked. It has been demonstrated that activation of the FcεRI receptor, which is located on the surface of basophils, mast cells and antigen-presenting cells, plays an essential role on immediate-type hypersensitivity and allergic diseases (15,16,22,23). Furthermore, genetic variability in its α and β subunits has been associated with increased IgE levels and the presence of atopic features (24,25). Previous data have also demonstrated a positive correlation between FcεRI receptor expression on inflammatory cells and serum IgE levels in a variety of disease states, such as asthma, atopic dermatitis and hyper-IgE syndrome (26). Similarly, this association also appears to be applicable to CSU, as demonstrated by our results. However, considering that CSU is not a classic allergen-driven disease, other factors might also have a significant influence on FcεRI receptor expression. An interesting finding from our study is the difference of the baseline expression of basophil FcεRI receptor between patients with CSU and HCs. Likewise, Metz et al (27) found higher baseline levels of FcεRI positive cells on cutaneous biopsies from patients with CSU compared to healthy subjects. These results, therefore,
would reflect the increased reactivity of inflammatory cells observed in subjects with active CSU, as a higher FceRI receptor expression would make those cells more sensitive to the stimulation by incoming triggers (4).

In patients with allergic rhinitis and asthma, clinical improvement during treatment with omalizumab has been related to a reduction in free IgE serum levels, and consequently, in the FceRI receptor expression on the immune effector cells surface, as IgE-free FceRI is structurally unstable and becomes internalized and degraded (22,28). This would lead to a reduction in the FceRI-mediated production of inflammatory cytokines and chemokines (2,15,16,23). Hence, this therapeutic down-regulation represents a unique molecular target whereby both the sensitization and the effector phases of the allergen-specific immune response could be inhibited (28). The fast in vivo onset of action of omalizumab in the treatment of these allergic diseases could also be explained by this mechanism. In this sense, Lin et al (15) observed a rapidly inhibited ragweed-induced nasal response in patients with allergic rhinitis within the first 7-14 days of treatment, which was associated with a marked reduction (96%) in free IgE serum levels within 3 days and in the basophil FceRI receptor expression within 14 days (70%). In CSU, however, this mechanism of action has not been extensively evaluated. Previously, Saavedra and Sur (29) reported a female patient with CSU successfully treated with omalizumab with a clear reduction (80%) in the basophil FceRI receptor expression after 14 days that was maintained throughout the duration of the treatment. In the present study we confirmed this assumption, as well as we found that the fast clinical improvement assessed through the PROs (UAS7 and UCT) was associated with a fast and sharp reduction in the basophil FceRI receptor expression within the first 4 weeks of therapy. In addition to our study on blood basophils, other investigations have evaluated the kinetic of omalizumab-induced
reduction in FcεRI receptor expression on skin mast cells from patients with CSU, and it seems that the time course for such down-regulation is slower on the tissue. Thus, levels of FcεRI positive skin cells in patients with CSU could decline to levels seen in healthy subjects after 12 weeks of treatment (27).

Because CSU represents a complex and multifactorial disease, seems reasonable to think that a unique pharmacologic mechanism could not fully explain the pattern of symptom improvement observed with omalizumab therapy. Some additional mechanisms of action have been proposed, including reversing basopenia and improving basophil FcεRI receptor sensitivity to allergen-driven secretion (17,30), alteration of the expression of genes associated with mast cell/leukocyte infiltration, oxidative stress, vascularization and skin repair events (31), reducing mast cell releasability (2,32), or reducing the activity of IgG autoantibodies by lowering the levels of available surface IgE and FcεRI receptor (27), among others. Thereby, given that subsets of patients with CSU may have different disease etiopathogenesis, the combination of more than one of the aforementioned mechanisms may explain the complete involvement of omalizumab in relieving symptoms associated with CSU (33).

Availability of reliable biomarkers of therapeutic response to different drugs in chronic diseases such as CSU might have an important impact in routine clinical practice. In this sense, for example, cyclosporine-treated CSU patients with a positive serum Basophil Histamine Release Assay (BHRA) showed higher rates of treatment response compared to those patients with negative BHRA (34). More recently, in a retrospective study of 41 patients with CSU the assessment of basophil CD203c-upregulating activity, which is thought to reflect the presence of autoantibodies to IgE and/or FcεRI receptor in the serum
of patients with CSU, has been found to be associated with the clinical response to omalizumab (35). However, none of these biomarkers are currently validated for their use in clinical practice.

In the present study we have observed that baseline expression of basophil FceRI receptor may represent a potential predictor of response to treatment with omalizumab in CSU. In fact, all patients who did not achieve clinical improvement with omalizumab had significant lower baseline levels of basophil FceRI receptor (and therefore a deficient down-regulation with the treatment) in comparison to responder patients, which would be the most likely explanation for the non-responder status. The reason why these patients show almost undetectable levels of basophil FceRI receptor is not yet fully understood. Genetic variability in the FceRI receptor could be a plausible explanation, since recent studies have shown that experimental molecular changes in the subunits of this receptor can affect its expression on the cell surface (36). Other authors have also observed basopenia in patients with more active CSU disease (37,38), which reflects the recruitment of basophils to skin tissue and might lead to a decrease expression of FceRI receptor on peripheral blood. However, in our cohort we did not find differences regarding the blood basophil count between responders and non-responders. Therefore, the practical value of basophil FceRI receptor expression as a clinically useful biomarker of omalizumab therapeutic response should be confirmed in future multicentre prospective studies. This fact would allow physicians to early identify patients who will not benefit from this treatment. It should be also taken into consideration that results of FceRI receptor expression assessed by flow cytometry could vary depending on the study population and technical issues. However, using a reference data from a control group of healthy subjects would allow a more accurate evaluation of the levels of this receptor in patients with CSU.
Although responder patients showed higher baseline total IgE levels in comparison to non-responders, there are not enough arguments to believe in the assessment of total IgE as a good therapeutic predictor in CSU. This is due to the wide range (and therefore overlap) of IgE values observed in responders (16-683 kU/L) and non-responders (1-100 kU/L). Thus, approximately 37% (14/38) of the patients showing satisfactory clinical improvement with omalizumab had baseline total IgE levels within the range observed in non-responders. Likewise, no predictive value has been found with this biomarker in other allergic diseases (39).

In summary, although further investigations are needed to fully understand the mechanism of efficacy of omalizumab in CSU, our study highlights the importance of the down-regulation of basophil FcεRI receptor expression in this process. The basophil FcεRI receptor expression holds promise as a clinically useful biomarker predicting response to omalizumab therapy. Thereby, low baseline levels would identify a special phenotype of CSU predicting a poor therapeutic response. While additional research should be conducted to further document these observations, the results shown in this study would have an impact in the management of CSU and contribute to understanding the clinical utility and mechanism of action of anti-IgE therapy.
ACKNOWLEDGEMENTS

The authors would like to thank Miguel Angel Descalzo (Research Unit, Fundación Piel Sana. Academia Española Dermatología y Venereología) for the statistical support, and Monica Giménez for helping with English editing and correction of the manuscript.
