Product Market Deregulation and the U.S. Employment Miracle*  

Monique Ebell† Christian Haefke‡ 

First Version: December 2002  
This Version: January 2006 

Abstract 

We consider the dynamic relationship between product market entry regulation and equilibrium unemployment. The main theoretical contribution is combining a job matching model with monopolistic competition in the goods market and individual wage bargaining. Product market competition affects unemployment by two channels: the output expansion effect and a countervailing effect due to a hiring externality. Competition is then linked to barriers to entry. We calibrate the model to US data and perform a policy experiment to assess whether the decrease in trend unemployment during the 1980’s and 1990’s could be attributed to product market deregulation. Our quantitative analysis suggests that under individual bargaining, a decrease of less than two tenths of a percentage point of unemployment rates can be attributed to product market deregulation, a surprisingly small amount.

1 Introduction

This paper studies the impact of product market deregulations on labor markets, with special emphasis on the Carter/Reagan deregulation of the late 1970’s and early 1980’s.

There has been quite some interest recently in the impact of product market institutions on labor markets. However, the focus of this literature has been to use differences in US and European product market regulation to try to explain the divergent performance of US and European labor markets over the 1980’s and 90’s. One obstacle faced by this literature is that the presence of a multitude of rigidities (and attempts at reform) in European labor markets makes it difficult to disentangle the roles of product and labor market institutions in accounting for high European unemployment rates. In contrast, the US labor market is both highly flexible and its institutions did not undergo any substantial reform during the period of interest. This allows us to focus only on changes in product market regulation, while holding labor market institutions constant.

Consider the graph of HP-trend unemployment rates in Figure 1.1 US unemployment rates began trending downward in the early 1980’s, falling from a peak of 7.6 % in 1982 to only 5.0 % in 2000. At the same time, the only significant change in US labor market institutions - the 1996 welfare reform - took place after most of the gains in unemployment had already been realized. Welfare reform was implemented between September 1996 and July 1997, and unemployment in 1996 had already fallen to 5.4 %.2 The deregulation of US product markets runs parallel to this decrease in unemployment, as shown by the OECD data on product market regulation plotted in Figure 1. This, together with the fact that deregulation took place around the time of the trend reversal in unemployment, makes it worth investigating whether product market deregulation could explain what has widely been termed the ‘employment miracle’ (Krueger and Pischke, 1997).

Indeed, there is some amount of empirical evidence to support the link between product market regulation and labor markets. At a micro level, Bertrand and Kramarz (2002) examine the impact of French legislation3, which regulated entry into retailing. They find that those regions (departements) which restricted entry more strongly, experienced slower rates of job growth. At the cross-country macro level, Boeri, Nicoletti and Scarpetta (2000), using an OECD index of the degree of product market regulation, also report a negative relationship between their countrywide regulation measure and employment. Fonseca, et. al. (2001) show that their index of entry barriers is negatively correlated with employment and positively correlated with unemployment rates. However, the high degree of correlation between labor and product market regulation documented in Nicoletti, Scarpetta and Boylaud (2000) makes it difficult to disentangle the effects of each type of regulation in a cross-country setup.

The main contributions of this paper are both quantitative and theoretical. Our main quantitative contribution is to show that the effect of product market deregulation on unemployment is surprisingly weak. In our baseline model, calibrated to match stylized facts of the US labor market, we find that increasing product market regulation from 1998 to 1978 levels can account for an increase of less than two tenth of a percentage point of unemployment, from 5.1% in 1998 to 5.24% in 1978. Our findings are highly robust to our choices of parameters and calibration targets.

On the theoretical side, we specify a dynamic general equilibrium model which combines monopolistic competition in the goods market with fully-microfounded unemployment arising from Mortensen-Pissarides-style matching frictions and individual wage bargaining between multiple-worker firms and workers. We identify two countervailing channels by which product market competition affects unemployment: the first-principles output expansion effect and the overhiring effect. From first principles, firms with monopoly

---

1We emphasize that these are trend unemployment rates, whose business cycle component has been filtered out.
2In fact, one might argue that the immediate transitory effect of welfare reform should have been to increase unemployment, as welfare recipients were pushed into the labor market.
3Loi Royer of 1974
power maximize profits by restricting output with respect to its full-competition level. As competition increases, profit-maximizing output expands, and along with it the demand for labor. This in turn implies a greater rate of vacancy creation, which leads to a lower rate of unemployment. The second channel is the countervailing overhiring effect, which arises due to the interplay of imperfect competition and individual bargaining in multi-worker firms.

First, note that the assumptions of multiple worker firms and individual bargaining are sensible ones to model changes in product market competition in the US economy. Under perfect competition in goods markets and constant returns to scale, the number and size of firms is indeterminate, so the one-worker firm assumption is innocuous. Under monopolistic competition, however, firm size is determinate, and varies according to the competition faced by the firm, making a multiple-worker setup preferable. Consistent with stylized facts of the US labor market, we also assume an ‘employment at will’ framework in which workers bargain individually with firms and firms cannot commit to long-term contracts. In such a setting, first analyzed by Stole and Zwiebel (1996, 1996a), the firm may choose to renegotiate the wage at any time with any worker, effectively making every worker the marginal worker. It is important to note that such a setup is the natural extension of paying marginal products to a framework with bargaining.

When every worker is the marginal worker, a hiring externality of the type first described by Stole and Zwiebel (1996, 1996a) can arise. When marginal revenue product is decreasing (as it is under imperfect competition), hiring an additional worker depresses the wages of all workers. This hiring externality gives firms an incentive to overhire, that is to hire workers beyond the point at which employment costs are recouped by marginal revenue product. The incentive to overhire is strongest when monopoly power is highest (i.e. when marginal revenue product is most steeply decreasing). As competition increases, overhiring is diminished, placing downward pressure on vacancy creation and counteracting the output expansion effect. Hence, neglecting this second overhiring channel might lead one to overestimate the potential benefits to product market reform.

Relatively little previous theoretical work has analyzed whether and how product market rigidities may affect equilibrium labor market outcomes. Nickell (1999) provides an insightful overview of early work which is either partial equilibrium or employing some form of collective bargaining. Recent important contributions are the papers of Blanchard and Giavazzi (2003) and Fonseca et. al. (2001), both of which find unemployment to be increasing in the degree of product market regulation. Fonseca et. al. (2001) focuses on the impact of entry barriers on the decision to become an entrepreneur or a worker, finding that entry barriers can indeed lead to lower rates of entrepreneurship and hence job creation. However, in their setup, those firms which have overcome the barriers to entry then face perfect competition. In contrast, Blanchard and Giavazzi (2003) study labor market outcomes in a model with monopolistic competition but with a more stylized labor-market setting. In a similar vein, Spector (2004) studies the effects of changes in the intensity of product market competition in a partial equilibrium model with capital and concludes that product-market and labor-market regulations tend to reinforce each other. The latter two papers consider static or two-period setups.

In theoretical terms, our paper is most closely related to Stole and Zwiebel (1996, 1996a), Smith (1999), Cahuc and Wasmer (2001), and Cahuc et al. (2004). Smith (1999) and Cahuc et al. (2004) present models with multiple-worker firms and individual bargaining with decreasing returns to scale, which also leads to an overhiring effect. Cahuc and Wasmer (2001) also illustrate that overhiring is not an issue under perfect competition and constant returns to scale, because marginal revenue product is constant. In addition, using a model without search frictions, Rotemberg (2000) argues that individual bargaining can lead to wages which are less procyclical than their neoclassical counterparts.

The remainder of the paper is organized as follows: Section 2 presents the basic model. Section 3 characterizes short and long-run equilibrium, and presents analytic results on the

\footnote{We discuss social efficiency in detail in section 5.}
impact of product market competition on labor market equilibrium. Section 4 focuses on quantitative analysis, and examines the ability of product market deregulation to account for the decline in US trend unemployment during the 80’s and 90’s. Section 5 explores the constrained efficiency properties of our model, while Section 6 concludes.

2 The Basic Model

In this section we present the basic general equilibrium model. Its main elements are monopolistic competition in the goods market and Mortensen-Pissarides-style matching in the labor market. Our innovation lies in defining and solving the multi-worker firm’s problem under monopolistic competition and individual bargaining. The households’ problems are standard. We restrict our analysis to the steady state.

2.1 Households

2.1.1 Search and Matching in the Labor Market

The labor market is characterized by a standard search and matching framework (e.g. Pissarides, 2000). Unemployed workers $u$ and vacancies $v$ are converted into matches by a constant returns to scale matching function

$$m(u, v) = s \cdot u^\eta v^{1-\eta}.$$  

Defining labor market tightness as $\theta \equiv \frac{v}{u}$, the firm meets unemployed workers at rate $q(\theta) = s\theta^{1-\eta}$, while the unemployed workers meet vacancies at rate $\theta q(\theta) = s\theta^{1-\eta}$.

Workers and firms are identical so that all jobs are identical. For each worker, the value of employment is given by $V^E$, which satisfies

$$rV^E = w - \chi [V^E - V^U]$$  

(1)

where $\chi$ is the total separation rate, $w$ denotes the per period real wage, and $V^U$ the value of being unemployed. Firms and workers may separate either because the match is destroyed, which occurs with probability $\tilde{\chi}$ or because the firm has exited, which occurs with probability $\delta$. We assume that these two sources of separation are independent, so that the total separation probability is given by $\chi = \tilde{\chi} + \delta - \tilde{\chi}\delta$. Explicit firm exit is incorporated mainly for quantitative reasons. If firms were counterfactually infinitely lived, then the impact of a given level of entry costs would be greatly understated, since firms could amortize those entry costs over an infinite lifespan.

The value of unemployment is standard:

$$rV^U = b + \theta q(\theta) [V^E - V^U]$$  

(2)

where $b$ denotes real unemployment benefits.

2.1.2 Monopolistic Competition in the Goods Market

Households are both consumers and workers. As consumers they are risk neutral in the aggregate consumption good. Agents have Dixit-Stiglitz preferences over a continuum of differentiated goods. Goods demand each period is derived from the household’s optimization problem:

$$\max \left( \int \frac{a_i}{c_{i,n}} \, di \right) \frac{a_i}{\sigma - 1}$$  

(3)

$^5$As is quite standard in the literature, $s$ denotes a scaling parameter which serves to bring matching rates within the $[0,1]$ interval, while $\eta$ denotes the elasticity of matches with respect to the number of unemployed.

$^6$We assume that all payments are made at the end of a period so that our value functions in discrete time actually coincide with their continuous time counterparts. Equation (1) can be obtained from

$$rV^E = \frac{1}{1+r} \left( w + (1-\chi) V^E + \chi V^U \right)$$
subject to the budget constraint $I_n = \int c_i P d\tilde{y}$ where $I_n$ denotes the real income of household $n$ and $c_{i,n}$ is household $n$’s consumption of good $i$. In order to focus the dynamics on the labor market, there is no saving. Thus we obtain aggregate demand for good $i$ given as:

$$Y_D^i = \int c_i d\tilde{y} = \left(\frac{P_i}{P}\right)^{-\sigma} I_n,$$  

(4)

where $I \equiv \int I_d d\tilde{y}$ is aggregate real income and $P = \left(\int P_1^{-\sigma} \right)^{1/\sigma}$ is the inverse shadow price of wealth, typically interpreted as a price index. Equation (4) is the standard monopolistic-competition demand function with elasticity of substitution among differentiated goods given by $-\sigma$.

### 2.2 Multiple-worker Firms

Firms are monopolistically competitive. We abandon the one-worker-per-firm assumption in favor of a more general framework with multiple-worker firms. Under perfect competition in goods markets and constant returns to scale, the one-worker firm assumption is harmless, since the number and size of firms is indeterminate. Under monopolistic competition, however, firm size is determinate, and varies according to the demand elasticity $\sigma$ faced by the firm, among others. The only way to vary firm size with a given technology is to vary the amount of labor employed either on the intensive margin or on the extensive margin. Consistent with stylized facts we assume that firms adjust employment by varying the number of workers [extensive margin] rather than the number of hours per worker.

Firms maximize the discounted value of future profits. Firm $i$’s state variable is the number of workers currently employed, $H_i$. The firm’s key decision is the number of vacancies. Firms open as many vacancies as necessary to hire in expectation the desired number of workers next period, while taking into account that the real cost to opening a vacancy is $\Phi V$. The firm’s problem becomes:

$$V^J(H_i) = \max_{H'_i \in \nu} \frac{1}{1+r} \left\{ P_i(Y_i) Y_i - w(H_i) H_i - \Phi V \nu_i + (1-\delta) V^J(H'_i) \right\}$$

(5)

subject to

- demand function: $P_1(Y_i) Y_i / P = \left(\frac{Y_i}{I}\right)^{1/\delta}$
- production function: $Y_i = A H_i$
- transition function: $H'_i = (1-\tilde{\chi}) H_i + q(\theta) \nu_i$
- wage curve: $w(H_i)$

where the wage curve is the result of individual bargaining as described in section 2.3.1.

The firm’s problem takes into account that a measure $\delta$ of firms exits each period.

The first order condition states that the marginal value of an additional worker must equal the cost of searching for him/her, weighted by the probability of firm survival $1-\delta$:

$$\frac{\Phi V}{q(\theta)} \frac{1}{1-\delta} = \frac{\partial V^J(H'_i)}{\partial H'_i}.$$  

(10)

---

7This argument is formalized in Cahuc and Wasmer (2001). Smith (1999) examines individual bargaining in a multi-worker firm under perfect competition and decreasing returns to scale, the other case in which the one-worker-per-firm assumption breaks down.

8In a model with capital, firms could also vary output by varying only the amount of capital employed. In order to maintain an optimal capital-labor ratio, however, firms would also generally adjust by varying labor as well.
Combining (10) with the envelope condition and using the definition of demand elasticity \( \sigma \equiv \frac{\partial Y_i}{\partial P_i} \) yields a simple mark-up expression:

\[
\frac{P_i(H_i)}{P} = \frac{\sigma}{\sigma - 1} \left\{ w(H_i) + \frac{qV_r}{Q(\theta)} \frac{r + \gamma}{1 - \delta} + H_i \frac{\partial w}{\partial H_i} \frac{1}{A} \right\}.
\]

Firms price their goods by taking a constant markup \( \frac{\sigma}{\sigma - 1} \) on the marginal cost of producing the good (the term in curly brackets). The first two terms of the marginal cost are standard, representing unit labor cost and annuitized search cost. The third term, \( H_i \frac{\partial w}{\partial H_i} \), reflects firms’ correct anticipation that the result of wage bargaining will depend upon the number of workers hired. In section 2.3 we will connect this final term to the hiring externality. In addition, it is useful to note that (11) is an implicit labor demand expression that relates the firm’s optimal employment choice to the wage.

2.3 Wage Bargaining

In this section we describe the wage bargaining, allowing us to generate wage curves and complete the description of labor demand. In the neo-classical framework, workers are paid their marginal products. The natural extension to a bargaining environment is the individual bargaining setup introduced by Stole and Zwiebel (1996). The key assumption of the individual bargaining framework is that firms cannot commit to long-term employment contracts, and may renegotiate wages with each worker at any time, making each worker effectively the marginal worker. The firm’s inability to commit is the key characteristic of the ‘employment at will’ environment dominant in US labor markets. Also, individual bargaining involves bargaining over wages only, since an individual worker can only deprive the firm of her own marginal product, which does not give the worker sufficient leverage to negotiate hiring.

We believe that this is the appropriate bargaining setup for our model for two further reasons. First, on theoretical grounds, individual bargaining is the natural extension of the Mortensen-Pissarides framework to multi-worker firms, because it ensures that Nash bargaining over wages is fully microfounded. In particular, Stole and Zwiebel (1996) show that individual bargaining may be understood as a Binmore-Rubinstein-Wolinsky (1986) alternating offer game. Hence the wage curve (15) can be obtained either by fully modeling the pairwise bargaining structure, or by solving a standard generalized Nash bargaining problem. Secondly, we later calibrate to US labor markets, in which "employment at will" is dominant, and which are hence better characterized by individual than by collective bargaining.

In the time period we consider, between 78 and 90% of private sector workers were not covered by a collective bargaining agreement, according to CPS data reported in Hirsch and Macpherson (2003).

2.3.1 Individual Bargaining Solution

Under individual bargaining, the firm’s outside option is not remaining idle, but rather producing with one worker less. The crucial point of the individual bargaining framework is that each worker is treated as the marginal worker, so that the bargaining problem becomes:

\[
\max_w \beta \ln \left( V^E - V^U \right) + (1 - \beta) \ln \frac{\partial V^J}{\partial H_i} \]

We know from e.g. Gul (1987) that symmetric Nash products can be used to compute the Shapley value. Following footnote 18 of Stole and Zwiebel (1996) but using a generalized sharing rule (with weight \( \beta \) for workers and \( 1 - \beta \) for firms), it is straightforward to derive a wage curve equivalent to our equation (12). In a companion paper, we compare our results to those derived under a collective bargaining framework, and show that assuming collective bargaining strengthens the impact of product market competition on unemployment and wages substantially.
To obtain an expression for firm’s surplus, take the envelope condition of the firm’s problem (5), and recall that the first order condition (10) implies that \( \frac{\partial V^J}{\partial H_i} \) be constant over time. This leads to:

\[
\frac{\partial V^J}{\partial H_i} = \frac{1}{r + \chi} \left( \frac{\sigma - 1}{\sigma} A P_i(H_i) - \frac{\partial w}{\partial H_i} H_i - w(H_i) \right).
\]

(13)

Substituting the expressions for worker’s and firm’s surplus (13) into the first order condition of (12) leads to a first-order linear differential equation in the wage

\[
w(H_i) = (1 - \beta) V^U + \frac{\sigma - 1}{\sigma - \beta} \frac{P_i(H_i)}{P} - \beta H_i \frac{\partial w}{\partial H_i}.
\]

(14)

It is straightforward to confirm that (14) has solution:

\[
w(H_i) = (1 - \beta) V^U + \frac{\sigma - 1}{\sigma - \beta} \frac{P_i(H_i)}{P}.
\]

(15)

Equation (15) is the wage curve under individual bargaining.\(^\text{11}\) We can now substitute out for the \( \frac{\partial w}{\partial H_i} \) term in (11) to obtain a labor demand function:

\[
w(H_i) = \frac{\sigma - 1}{\sigma - \beta} \frac{P_i(H_i)}{P} - \Phi \frac{V}{q(\theta)} \left( r + \frac{\chi}{1 - \delta} \right).
\]

(16)

Equation (16) can also be interpreted as a job creation condition. As expected, it is downward sloping, both in the amount of labor demanded \( H_i \) and in labor market tightness \( \theta \).

### 2.4 Firm-level Equilibrium

In this section, we find the firm’s optimal employment-wage pair when it takes the aggregate variables (labor market tightness \( \theta \) and competition \( \sigma \)) as given.

**Definition 1** Firm-Level Equilibrium

A firm-level equilibrium is defined as a pair of real wages and firm-level employment \( H_i \) which satisfies both labor demand (16) and the individual bargaining wage curve (15), taking aggregate variables \( (\theta, \sigma, I) \) as given.

This firm-level equilibrium is found at the intersection of labor demand (16) and the wage curve resulting from individual bargaining (15), as illustrated in Figure 2. Formally, we obtain:

\[
A \frac{P_i(H_i)}{P} = \frac{\sigma - 1}{\sigma - \beta} V^U + \frac{1}{1 - \beta} \frac{\Phi \ V}{q(\theta)} \left( \frac{r + \chi}{1 - \delta} \right)
\]

(17)

\[
w(\theta) = V^U + \frac{\beta}{1 - \beta} \frac{\Phi \ V}{q(\theta)} \left( \frac{r + \chi}{1 - \delta} \right)
\]

(18)

Equation (17) expresses firm-level employment implicitly, while equation (18) gives the firm-level equilibrium wage. Also note that although firm-level equilibrium wages do not depend explicitly on \( \sigma \), they will depend on competition indirectly, via equilibrium labor market tightness \( \theta \).

### 2.5 Hiring Externality

The individual bargaining solution presented above displays a hiring externality of the type first explored in partial equilibrium by Stole and Zwiebel (1996a). To see this, first recall that in the standard one-worker-one-firm setup, marginal (revenue) product is equated to the cost of employing a worker in equilibrium. In our case, however, this equilibrium

\(^\text{11}\) The differential equation is solved in appendix D
relationship is modified by the presence of an overhiring term. Specifically, rearranging the firm-level equilibrium employment equation yields:

\[
\frac{\sigma - 1}{\sigma} \frac{A}{P} P(H_i) = \frac{\sigma - \beta}{\sigma} V'H_i
\]

Equation (19) equates the firm’s marginal revenue product to the cost of employing a worker [equal to the wage plus the hiring cost], multiplied by an overhiring factor \(\frac{\sigma - \beta}{\sigma} < 1\). \(^{12}\)

The overhiring factor \(\frac{\sigma - \beta}{\sigma} < 1\) expresses the fact that firms optimally hire workers beyond the point at which employment costs can be recouped by the worker’s marginal product. Firms are willing to employ workers whose marginal revenue product is not high enough to cover their employment costs, because hiring these workers confers an added non-MRP benefit to firms. This added benefit or hiring externality arises because hiring more workers when MRP is declining serves to depress the wages of all workers. This can be seen from the labor demand equation (11):

\[
\frac{\sigma - 1}{\sigma} \frac{A}{P} P(H_i) = w(H_i) + \Phi V' q(\theta) \left( \frac{r + \chi}{1 - \delta} \right) + H_i \frac{\partial w}{\partial H_i}
\]

The hiring externality term represents the wage impact of adding an extra worker, multiplied by the total number of workers. The negative hiring externality term reflects the fact that adding a worker depresses the wages of all workers, since all workers are treated as the marginal worker. Formally:

\[
H_i \frac{\partial w}{\partial H_i} = -A \frac{\beta}{\sigma} \left( \frac{\sigma - 1}{\sigma - \beta} \right) P_i < 0
\]

From (21), it is easy to see that the hiring externality is strongest when competition \(\sigma\) is low and worker bargaining power \(\beta\) is high. In the perfect competition limit, as \(\sigma \to \infty\), the hiring externality disappears because MRP is constant. The hiring externality is also zero if worker bargaining power \(\beta\) equals zero.

The reason that overhiring is increasing in monopoly power is simple: The stronger is monopoly power, the more steeply decreasing is marginal revenue product, so hiring an additional worker depresses wages more strongly. Hence, monopoly power increases the size of the hiring externality and drives up overhiring. In this way, the hiring externality works to dampen the negative first order effects of monopoly power on employment. When monopoly power increases, the first principles effect leads firms to decrease output and hence employment. Under high monopoly power, however, firms’ incentive to overhire in order to depress wages is relatively strong, and serves to counteract the first principles effect. In some sense, then, overhiring ameliorates the negative output- and employment-restricting effects of monopoly power. Just how much the overhiring effect is able to counteract these first principles effects of monopoly power is a quantitative question which we address in section 4.

Overhiring is also increasing in workers’ bargaining power \(\beta\). This is intuitive, since the average higher wages which accompany greater worker bargaining power give the firm an added incentive to depress wages.

In section 5, we will show formally that the hiring externality leads firms to hire more than the constrained socially efficient number of workers. This is analogous to the overhiring results in Stole and Zwiebel (1996a) and Smith (1999). In Smith (1999) and Stole and Zwiebel (1996a), however, the source of decreasing MRP is not monopoly power but

\(^{12}\)This breakdown is analogous to that Cahuc et. al. (2004).
decreasing returns to scale in production. Also, our finding that the overhiring effect dis-
appears under perfect competition is in line with the results of Cahuc and Wasmer (2001),
who show that the hiring externality is absent in a model with constant returns to scale and
perfect competition.

3 General Equilibrium

We proceed to find equilibrium in two steps. First, we find the short run general equilib-
rium, which amounts to finding the equilibrium degree of labor market tightness \( \theta \) while
holding the degree of competition \( \sigma \) facing the firms constant. This will allow us to obtain
expressions for all equilibrium variables as functions of competition \( \sigma \). In a second step,
we will introduce entry costs, which will serve to endogenize the degree of competition in
the economy. This last equilibrium will be referred to as long-run general equilibrium.

3.1 Short Run General Equilibrium

Now, we determine the short-run general equilibrium, taking as given the degree of com-
petition. In our setting, this is equivalent to pinning down all equilibrium variables as
functions of the degree of competition \( \sigma \). This will allow us to determine the impact of in-
creasing competition on equilibrium unemployment and wages. We assume a continuum
of identical firms that are uniformly distributed over the unit interval.

Definition 2 Short-run General Equilibrium

A short-run general equilibrium is defined for given \( \sigma \) and parameters
\((\beta, b, \Phi_\nu, \delta, \chi, r, A)\) as a value of \( \theta \) which:

(i) is a firm-level equilibrium satisfying (17)-(18)
(ii) satisfies the following aggregate resource constraint

\[
I = \frac{P(Y)}{p} Y. \tag{22}
\]

Substituting in from (17), using (6) and (7) to substitute out for \( H_t \) and getting a closed
form solution for \( rV^U \) from (1), (2) and (18) leads to the short-run equilibrium condition

\[
A = \frac{\sigma - \beta}{\sigma - 1} \left( b + \frac{\beta}{1 - \beta} \frac{\Phi_\nu \theta}{1 - \delta} + \frac{1}{1 - \beta} q(\theta) r + \chi \right). \tag{23}
\]

The short-run general equilibrium condition (23) is monotonically increasing in \( \theta \), so that
existence of equilibrium is guaranteed if

\[
A > \frac{\sigma - \beta}{\sigma - 1} b. \tag{24}
\]

When the economy approaches full competition [as \( \sigma \to \infty \)], (24) reduces to the standard
condition \( A > b \) that workers’ productivity be greater in employment than in unemploy-
ment.

Equation (23) is key, since it relates the degree of competition \( \sigma \) to short-run equilibrium
labor market tightness \( \theta \). Once we have \( \theta(\sigma) \), we can obtain the short-run equilibrium
unemployment rate from the Beveridge curve:

\[
u(\sigma) = \frac{\chi}{\chi + \theta[\sigma] q(\theta[\sigma])}. \tag{25}\]
The remainder of equilibrium variables are found as follows. First, note that equilibrium reservation utility is given by:

\[ rV^U = b + \frac{\beta}{1 - \beta} \frac{\Phi \theta}{1 - \delta}. \]  

(26)

Given the total number of agents in the economy \( N \), we can find equilibrium aggregate employment as \( H(\sigma) = N[1 - u(\sigma)] \). We will find it convenient to normalize \( N = 1 \). With \( H(\sigma) \) in hand, we can find aggregate output and subsequently the equilibrium quantity of goods, and of course short-run equilibrium employment per firm \( H_i(\sigma) \) \(^{13}\) and price \( P_i(\sigma) \), all in terms of the given degree of competition. A complete list of all short-run equilibrium equations can be found in appendix D.

3.1.1 Comparative Statics I: Varying Competition

The characterization of short-term equilibrium allows us to examine the qualitative impact of varying the degree of competition \( \sigma \) on short-term equilibrium unemployment and wages. We identify two main channels by which an increase in competition affects employment and unemployment: (1) the first principles output-expansion channel, which has been discussed by Blanchard and Giavazzi (2003) and (2) the hiring externality channel, which is unique to our analysis of product market deregulation. Via the output expansion channel, increased competition leads to increased employment and decreased unemployment, while the hiring externality channel works in the opposite direction.

Expanding equation (23) allows us to examine these two channels formally:

\[ A = \frac{\sigma - \beta}{\sigma - 1} \left( b + \frac{\beta}{1 - \beta} \frac{\Phi \theta}{1 - \delta} \right) + \frac{\Phi \theta}{1 - \beta} \left( r + \frac{\sigma}{\beta} \right). \]  

(27)

The output expansion term is simply the markup of the monopolistically competitive firm. The greater is monopoly power, the greater is the markup \( \frac{\sigma}{\sigma - 1} \), the smaller is equilibrium tightness \( \theta \). By the Beveridge curve, equilibrium unemployment is decreasing in tightness, so that greater monopoly power leads to higher unemployment. The overhiring term counteracts the output expansion term. The greater is monopoly power, the smaller is the overhiring term, the greater is equilibrium tightness \( \theta \) and the lower is unemployment. These two effects are illustrated in Figure 3, which shows the contribution of the overhiring and output expansion effects to equilibrium tightness. The solid line shows the impact of competition on equilibrium labor market tightness \( \theta \) that is solely due to the output expansion effect, that is, when the hiring externality has been shut down by setting \( \frac{\sigma}{\sigma - 1} = 1 \). Accordingly, the dashed line shows the impact of competition on \( \theta \) that can be attributed solely to the hiring externality, i.e. when the output expansion effect has been shut down by setting \( \frac{\sigma}{\sigma - 1} = 1 \).

The combined effect of output expansion and overhiring is given by \( \frac{\sigma - \beta}{\sigma - 1} > 1 \), so that the net effect of increasing monopoly power (i.e. decreasing \( \sigma \)) is to increase unemployment. Clearly, however, since \( \frac{\sigma - \beta}{\sigma - 1} < \frac{\sigma}{\sigma - 1} \), the increase in unemployment is smaller than it would be in the absence of the overhiring effect. By just how much overhiring dampens the impact of monopoly power on unemployment is a quantitative question which we will address in the next section.

This comparative static result for short-term equilibrium is summarized in Lemma 1 and Proposition 2. All proofs are found in appendix A.

**Lemma 1** Short-run equilibrium labor market tightness is a strictly increasing function of demand elasticity \( \sigma \).
Proposition 2 In short-run equilibrium:
(i) unemployment is strictly decreasing in competition $\sigma$,
(ii) wages are strictly increasing in competition $\sigma$.

Proposition 2 also establishes that equilibrium wages are increasing in the degree of competition. This conclusion is the opposite of that drawn by the recent literature on wages and the sharing of monopoly rents (e.g., van Reenen, 1996). The source of the disparity is that the rent-sharing papers typically look at only one isolated industry, while we consider broader increases in competition which affect all industries at once. The general equilibrium effect of greater competition is to increase vacancies and tightness in all sectors, making it easier for unemployed workers to find new jobs. This increases the value of the worker’s reservation utility $rV^U$, thereby improving the worker’s bargaining position and increasing his/her wage, as illustrated by equation (26) in conjunction with Lemma 1. In addition, equilibrium match surplus, given by $\frac{b}{1-\beta} \Phi b rV^U$, is also increasing in competition. The reason is that in equilibrium the value of the marginal worker is equal to the cost of searching for him/her, which must increase with $\theta$. Hence, equilibrium wages are increasing in competition. This is similar to the positive wage effect of competition found by Blanchard and Giavazzi (2003). It is also consistent with data on labor shares (simply computed as employee compensation over GDP) and entry regulation, as illustrated in Figure 4.

3.1.2 Comparative Statics II: Varying Parameters

Proposition 3 summarizes the impact of varying parameters on short-run equilibrium.

Proposition 3 Effects of parameters on equilibrium $\theta$ and unemployment
In short-run equilibrium:
(i) labor market tightness $\theta$ is decreasing in the parameters $b$, $\Phi V$, $r$, $\delta$, and $\tilde{\chi}$;
(ii) unemployment is increasing in the parameters $b$, $\Phi V$, $r$, $\delta$ and $\tilde{\chi}$;
(iii) labor market tightness $\theta$ is decreasing in $\beta$ and unemployment is increasing in $\beta$ if either $b < \frac{\Phi V}{\frac{1}{\beta} \Phi V} \theta$ or $b \geq \frac{\Phi V}{\frac{1}{\beta} \Phi V} \theta$ and $\sigma \geq \tilde{\sigma}$ where $\tilde{\sigma} = \frac{\Phi V}{\frac{1}{\beta} \Phi V} \frac{b(1-\beta)^2 + \frac{\Phi V}{\frac{1}{\beta} \Phi V} \theta + \frac{\Phi V}{\frac{1}{\beta} \Phi V} \delta}{\frac{1}{\beta} \Phi V}$.

The results of parts (i) and (ii) of Proposition 3 are standard for search and matching models. Part (iii) merits comment. Unemployment’s reaction to an increase in workers’ bargaining power is standard, unless the degree of competition is very low. The intuition is that higher workers’ bargaining power strengthens the overhiring effect, in the sense that $\frac{\partial \phi w}{\partial \phi b} < 0$ for given $H_i$ and $P_i$. At very low levels of competition, the overhiring effect discussed in section 2.3 is particularly strong. In this case, increasing bargaining power strengthens the overhiring effect so much [i.e., increasing firms’ incentives to hire more workers to depress wages], that the end result is lower unemployment.

3.2 Long-run General Equilibrium

Now we are ready to endogenize the degree of competition. In the long-run, firms may enter each industry by paying a real entry cost $\Phi E$ and by posting enough vacancies to hire the steady-state workforce. The details of firm entry and exit are as follows: Each period a measure $\delta$ of firms exits, and is replaced by a measure $\delta$ of new entrants. New entrants begin production immediately with their steady-state workforce. Hence, we assume that entering firms know far enough in advance that they will be entering to complete all entry formalities. During this (these) pre-entry period(s) firms pay the entry cost and post enough vacancies to hire their steady-state workforce. Entry by firms will continue until

---

14 Note that it is not necessary to take the measure $\delta$ of pre-entry firms into account in aggregate income. They do not yet produce and only incur vacancy costs. Hence the firm’s profits and vacancy costs sum to zero.
profits net of entry costs within each industry have been competed down to zero. Hence, free entry in the presence of barriers to entry leads to equilibrium demand elasticity $\sigma^*$, which is defined implicitly by:

$$
\Phi_E (\sigma^*) + \Phi_V \frac{H_i (\sigma^*)}{q(\theta (\sigma^*))} = V^f [H_i (\sigma^*)]
$$

The free entry condition (28) states that the entry cost must be amortized by profits over the firm’s expected lifespan. Since equilibrium profits are decreasing in competition, free entry forges a negative link between barriers to entry and the degree of competition in the economy.\(^{15}\)

Entry barriers may take two complementary forms, time and pecuniary costs. For 1997 we have detailed data on the number of business days it takes to set up a standardized firm from the OECD as reported by Pissarides (2001) and on entry fees as a percentage of per capita GDP from Djankov, et al. (2002). We combine the two measures into a single one by adding up the entry costs as a percentage of per capita annual GDP and the fraction of a year which is lost to entry delay. This implicitly treats the entry delay as a loss of the fraction of annual per capita GDP which would have been produced during that time period.

Formally, total barriers to entry are found as:

$$
\Phi_E (\sigma) = [d + f] \cdot I (\sigma).
$$

(29)

where $d$ is the regulatory delay in months and $f$ are entry fees as a share of aggregate monthly income. Combining (29) with the free entry condition (28) yields:

$$
[d + f] \cdot I (\sigma^*) + \Phi_V \frac{H_i (\sigma^*)}{q(\theta (\sigma^*))} = V^f [H_i (\sigma^*)]
$$

(30)

Equation (30) closes the long-run equilibrium. It determines the endogenous degree of competition $\sigma^*$ in long-run equilibrium by defining a negative relationship between barriers to entry and the degree of competition in long-run equilibrium.

### 3.3 Balanced Budget

For our quantitative experiments we augment the model to allow for unemployment benefits to be financed by equal magnitude income and payroll taxes ($\tau_I, \tau_P$). The resulting balanced budget condition is:

$$
(\tau_I + \tau_P)w(1-u) = bu.
$$

(31)

It is straightforward to confirm that the short-run equilibrium condition (23) becomes:

$$
A = \frac{\sigma - \beta}{\sigma - \delta} \left( \frac{1 +\tau_P}{1 - \tau_I} \right) b + \frac{\beta}{1 - \beta} \frac{\Phi_\theta}{1 - \delta} + \frac{1}{1 - \beta} \frac{\Phi_V}{q(\theta)} \left( r + \chi \right).
$$

(32)

All other equilibrium equations under taxation and a balanced budget are presented in appendix E.

\(^{15}\)To forge an explicit link between barriers to entry and the number of firms, one may take two routes. First, one may follow Blanchard and Giavazzi (2003) and assume that $\sigma$ is an increasing function of the number of firms. Alternatively, one may hold $\sigma$ constant, and allow for $n$ firms competing via Cournot in each industry. In a previous version of this paper, we followed this second setup. Results are very similar to those of the simpler setup presented here, and are available upon request.
4 Quantitative Results

We are now in a position to calibrate our model and approach our quantitative questions. We first explain in detail how we calibrate the basic model to match a set of labor market data from the United States. Then, for this calibration we ask: What is the impact of increasing competition on equilibrium unemployment and wages? In order to answer this question, we run a policy experiment which is designed to assess whether the product market deregulation of the late 1970’s and 1980’s could account for the decline in US unemployment during the 1980’s and 1990’s. Finally, we go on to quantify the overhiring effect.

4.1 Calibration

One model period is one month. All parameters are reported in Table 4. We first calibrate the model to US data in 1998. We use estimates from the literature to guide our choices for the first group of parameters. The bargaining power of workers, $\beta$, has recently been estimated between 20% (Cahuc, Gianella, Goux and Zylberberg, 2002) and 50% (Abowd and Allain, 1996, Yashiv, 2001). Petrongolo and Pissarides (2001) report $\eta$, the elasticity of the matching function with respect to unemployment, to be in the range of [0.5;0.7]. We set $\beta = \eta = 0.5$, thus choosing standard values and imposing the Hosios (1990) condition. For simplicity, we normalize the level of technology $A_{08}$ to unity. Our choice of 40% for the annualized real interest rate is standard, as our choice of the flow utility of unemployment $b$, which is consistent with a replacement rate of 50%.

We choose the remaining parameters to match some stylized labor market data for the U.S. in 1998. Specifically, we replicate the 1998 HP-trend value for the unemployment rate of 5.1% and set the job finding rate to be 0.45 following Shimer (2005). We normalize the firm’s matching rate so that the vacancy duration is 4.2 months as in den Haan, Ramey and Watson, (2000). Our choices for unemployment duration and vacancy duration restrict US equilibrium labor market tightness to be $\theta = \frac{\lambda_w}{\lambda_f} = 1.89$, where $\lambda_w$ and $\lambda_f$ are the matching rates of workers and firms respectively. This figure looks high at first glance. However, before comparing it to standard one-worker firm models and data it is necessary to adjust for the fact that firms open as many vacancies as necessary in order to fulfill their hiring needs in expectation. If we multiply the equilibrium tightness $\theta$ with the firm matching rate we find a ratio of open jobs to unemployed of 45%. The equality of tightness with the job-finding rate is in line with the findings of Shimer (2005). Finally, the scaling parameter of the matching function $s$ must satisfy $s = \frac{\lambda_f}{\lambda_w}$. The exogenous total separation rate $\chi = 2.4\%$, is pinned down by the Beveridge curve in conjunction with our values for unemployment and unemployment duration. We set $\delta = 0.8\%$, so that the monthly probability that a firm will cease to exist implies an annual firm survival rate of 90.8%. This matches the average five-year survival probability reported by Wagner (1994) and is in line with the four-year firm survival probabilities reported in Mata and Portugal (1994), which imply monthly exit rates between 0.6 and 1.4%.

We are left with a short-run equilibrium condition which relates the above-mentioned parameters and variables to vacancy posting costs $\Phi_V$, and with a long-run equilibrium condition (30) which relates $\Phi_V$ to firm’s demand elasticity $\sigma$. We pin down $\sigma$ by the entry costs and the vacancy cost $\Phi_V$ by the unemployment rate. We choose that level of vacancy posting costs which leads to a long-run equilibrium U.S. equilibrium unemployment rate of 5.1%. This yields a value of $\Phi_V = 0.24$, so that hiring costs per worker are $\frac{\sigma}{\Phi_V} = 1.01$ units of output, which corresponds to slightly more than a worker’s monthly wage.

---

16We wish to concentrate on the long-run impact of regulation, abstracting from business cycle considerations. Hence, we use the HP-trend value, in which the business cycle component has been filtered out.

17Pinning down the value of $\theta$ does not fully describe short-run equilibrium, as long as some other variable is left free. In our case, this variable will be $\Phi_V$. 

---
For 1997, we can use the detailed entry cost data reported in Table 1, resulting in entry costs corresponding to 0.6 months of aggregate per capita income. For 1978 there is no such entry cost data available. However, Nicoletti and Scarpetta (2001) have compiled an index on product market regulation for a set of 21 countries whose starting date is 1978 and whose ending date is 1998. These 1998 and 1978 index values are displayed in Table 2 for the subset of 17 countries for which both the index and the detailed entry cost data are available. In order to estimate US entry costs for 1978, we use the following 'triangulation' procedure. We first note that the correlation between Nicoletti’s index in 1998 and our composite measure of entry costs is very high at 0.77. To estimate entry costs in 1978, we run the following regression:

$$\text{entry costs}_{1997,i} = \alpha + \beta \cdot \text{regulation index}_{1998,i} + \epsilon_i$$

where \(i\) represents the country. We then combine the resulting regression coefficients (reported in Table 3) with Nicoletti’s index values for 1978 to obtain an estimate for 1978 entry costs of 5.2 months of aggregate per capita income.

Finally, our calibrations are for a balanced budget version of the model in which unemployment benefits are financed by equal magnitude income and payroll taxes \((\tau_I, \tau_P)\). In the 1998 US model economy, income and payroll taxes of 1.3 % are necessary to finance unemployment benefits.

### 4.2 Product Market Competition and the Labor Market

The results of this calibration are presented in Figure 5. The middle right panel shows that profits and the US entry costs for 1998 are equalized when demand elasticity is 81.4, which corresponds to a markup of 0.6 %, while the upper right panel shows that long-run equilibrium in 1978 occurs at a demand elasticity of 9.1, corresponding to a markup of 6.2 %.\(^{18}\) The upper left panel shows that unemployment could increase by maximally 2 percentage points due to an increase in monopoly power to the highest amount which is consistent with existence of equilibrium. Real wage decreases due to increases in monopoly power, on the other hand, could be very substantial, as shown in the middle left hand panel of Figure 5. The lower panels show that most of the wage increases due to increases in competition are due to improvements in the workers’ reservation utility. This in turn has its origins in the increases in labor market tightness due to increased competition, which make it easier for workers to find jobs when unemployed, increasing their reservation utility. Hence, under individual bargaining there is little adjustment to monopoly power via equilibrium unemployment (and hence output), but the impact on wages and profits is substantial.

We note that the bulk of the impact of monopoly power on wages and unemployment occurs under very low levels of demand elasticity. This is consistent with the empirical results of Bresnahan and Reiss (1991), who find that most of the benefits due to increased competition come from the entry of the first three to five competitors, with very little benefits accruing to further entry.

### 4.3 A Simple Policy Experiment

We now use the balanced budget version of the model to run a simple policy experiment, in order to assess to what extent product market deregulation can account for the decline in U.S. unemployment during the 80’s and 90’s. We do this by starting with the model calibrated to match US HP-trend labor market data in 1998,\(^{19}\) and then examining the impact of changing the entry costs to reflect those of 1978. We emphasize that we calibrate to labor

\(^{18}\)Since the model yields a US markup for 1998 which is quite small, we also present alternative calibrations in which entry costs are factored up so that the US markup in 1998 are 5.0 % and 10.0 %. Details may be found in section 4.4.2.

\(^{19}\)Once again, we emphasize that we calibrate to labor market data from which the business cycle component has been filtered out.
market data from which the business cycle component has been filtered out, in order to focus on the long-run impact of a change in product market regulation.

Results of the policy experiment are presented in Table 5. In the baseline calibration, changes in product market regulation can only account for a surprisingly small change in equilibrium unemployment. Raising entry costs nearly tenfold to their 1978 level leads to a decrease in competition, causing markups to increase by a factor of 10, to 6.2%, but resulting in an increase in unemployment of only one-tenth of one percentage point. As a result of the decrease in competition, unemployment increases only very slightly, from 5.1% to 5.24%. In contrast, in the data, trend unemployment increases from 5.1% in 1998 to 7.1% in 1978, as shown in Figure 1.

The reason for the weak impact of product market institutions on unemployment rates can be traced to the interaction of the two countervailing effects, output expansion and the hiring externality. The hiring externality inherent in the individual bargaining setup effectively counteracts much of the detrimental impact of monopoly power on unemployment.

4.4 Robustness

We now proceed to check the robustness of our quantitative results. We first vary the calibration targets for the job-filling and job-finding rates and for the replacement rate, the monthly rate of firm exit, and the matching elasticity $\eta$ and bargaining power $\beta$. We find that our choice of these parameter values is innocuous and has only negligible effects on the results that we report. We also consider the possibility that our entry cost data is systematically underestimating barriers to entry, and recalibrate the model to match 5.0% and 10.0% markups. We find that the only way to generate a substantial impact of entry costs on unemployment is by multiplying both the 1998 entry costs and the gap between 1978 and 1998 entry costs by a factor of 6. Increasing the difference in entry costs by this margin, however, leads to counterfactually large movements in wages.

4.4.1 Setup

We take the calibration to the U.S. economy in 1998 as a starting point and vary the variable of interest over a wide range of values. For each of these values we recalibrate the model to still fit the remaining baseline calibration targets of a 5.1% unemployment rate, 45% job-finding rate, 4.2 months vacancy duration and a replacement rate of 0.50. We then repeat the policy experiment and report the results.

4.4.2 Results

We first examine the impact of varying the calibration targets for the job-finding rate. Our alternative targets match the 1998 HP-trend values for the mean and median unemployment durations, leading to job-finding rates of 0.31 and 0.67. As shown in Table 6, the impact on the policy experiment results are barely perceptible. Similarly, the results of the policy experiment are highly robust to varying the job-filling rate targets, as reported in Table 7.

Next, we vary the target value for the replacement rate widely, increasing it to 70% and decreasing it to 30%. Once again, we find that the results of our policy experiment are very robust to the choice of replacement rate. The impact of increasing the replacement rate to a counterfactually high 70% would be to decrease the 1978 unemployment rate by one one-hundredth of a percentage point, as shown in Table 8.20

Our results are also quite robust to the choice of the firm exit rate $\delta$ and the matching elasticity/bargaining power parameters $\eta = \beta$. Table 9 shows that increasing the monthly

---

20Note that we recalibrate $\Phi_{1998}$ to match a 5.1% unemployment rate in 1998. Otherwise, the higher replacement rate would shift both 1998 and 1978 unemployment rates upwards, while leaving the gap between the two (our variable of interest) nearly unaltered.
firm exit rate by one-tenth of a percentage point (causing the annual firm exit rate to increase by about one percentage point) leads to an increase in the unemployment change generated by our policy experiment of only about one one-hundredth of a percentage point, a negligible quantity. Table 10 repeats the policy experiment for alternative values of matching elasticity and bargaining power.\textsuperscript{21} We vary $\eta = \beta$ between 0.30, at the lower bound of matching elasticity estimates reported in Petrongolo and Pissarides (2001), and 0.72, as recently estimated for US data by Shimer (2005). Increasing $\eta = \beta$ to 0.72 causes the unemployment impact to decline further, to less than one tenth of one percentage point, while decreasing $\eta = \beta$ to 0.30 causes the unemployment impact of the decrease in product market regulation to increase somewhat to two tenths of a percentage point. The reason is that decreasing $\eta$ increases the curvature of the Beveridge curve, increasing the impact of a given change in labor market tightness on unemployment. In addition, the strength of the overhiring effect is increasing in $\beta$, so that decreasing bargaining power will allow the output expansion effect to come out more strongly. Nonetheless, the quantitative impact of varying $\eta$ and $\beta$ is quite small.

Finally, one possible criticism of our calibration approach is that the resulting markups are quite small, while it is only under the high markups associated with a great deal of monopoly power that competition can have any noticeable impact on unemployment. (cf. Figure 5). Although there is some evidence that markups and profits are indeed close to zero (cf. Basu and Fernald (1997) and Rotemberg and Woodford (1995)), we do wish to ensure that our results are robust to markups in the range of 5 to 10%. In order to generate such higher markups, we must scale up the entry costs. We do this in two ways. First, we add the same constant $\gamma_a$ to entry costs in 1998 and 1978. We interpret $\gamma_a$ as representing some other types of barriers to entry which have remained constant over time. We also factor up the entry costs by multiplying both the entry costs in 1998 and 1978 by the same constant $\gamma_m$. We interpret $\gamma_m$ as representing some other types of barriers to entry which are proportional to the entry costs captured in the data. The main difference between the additive and multiplicative scaling up of entry costs is that the additive approach keeps the difference between entry costs at 1998 and 1978 constant, while the multiplicative approach also factors up that gap by $\gamma_m$.

The results of calibrating to markups of 5 and 10% are reported in Tables 11 and 12. Our results are highly robust to adding a constant term $\gamma_a$ to entry costs at both dates, as the unemployment impact in the policy experiment is virtually unchanged. Multiplying entry costs at each date by a constant $\gamma_m$ which is sufficiently large so as to generate 5 and 10% markups in 1998 does affect the policy experiment results substantially. When $\gamma_m = 3.42$, so that the equilibrium markup in 1998 is 5.0%, the impact of the product market deregulation is still only about one half of one percentage point. When $\gamma_m = 6.1$, so that the equilibrium markup in 1998 is 10.0%, we find that the impact on unemployment of a product market deregulation rises to over one full percentage point. Although this might prima facie be taken as evidence that a product market deregulation could have been responsible for a non-negligible portion of the decrease in unemployment over the 80’s and 90’s, there are two important reasons to shun this interpretation. First, obtaining a 10.0% markup involves not only multiplying the level of entry costs by a factor of six, it also involves multiplying the change in entry costs between 1998 and 1978 by a factor of six. Secondly, and perhaps more importantly, the relatively large increase in unemployment is accompanied by very large and counterfactual wage changes. In particular, the real wage would have to have increased by more than 50% between 1978 and 1998. Hence, we conclude that there is no reasonable calibration of the model that allows us to obtain a large impact of entry costs on unemployment.

To sum up, our reported result that increasing the regulation of entry to the U.S. product market to 1978 levels has only negligible employment consequences is consistent with a wide array of choices for our calibration targets and parameters and is by no means a

\textsuperscript{21}We impose the Hosios condition that $\eta = \beta$ throughout. In our setting, the Hosios condition is necessary but not sufficient for efficiency, as shown in the following section.
special case.

4.4.3 Quantifying Overhiring

In the policy experiment, we saw that the impact of monopoly power on unemployment was surprisingly small. In order to assess which role the hiring externality is playing in counteracting the first principles output expansion effect of increasing competition, we proceed to quantify the overhiring effect. To do this, we use the decomposition of equation (19) in order examine the quantitative consequences of shutting down the hiring externality. We find the equilibrium in the absence of overhiring by setting the overhiring term \( \frac{\sigma - \beta}{\sigma} = 1 \), which guarantees that firm-level equilibrium equates marginal revenue product and employment cost [wages plus hiring costs], as would be the case in a standard one-worker-firm matching model. The baseline results are plotted in Figure 6. The top panel compares the unemployment rate when the overhiring effect is operative and when it is shut down, while the bottom panel plots the corresponding difference in unemployment rates. Clearly, at very high levels of monopoly power the overhiring effect leads to reductions of unemployment of up to five full percentage points.

The bottom panel of Figure 6 shows the impact of overhiring on net wages. Although the source of the overhiring effect is individual firms’ desire to depress wages, the aggregate effect of the hiring externality is to increase wages. The reason is that the expanded hiring and the posting of more vacancies makes it easier for workers to find jobs, increasing their reservation utility and thereby boosting their equilibrium wages.

Analogous to the robustness results presented in the previous subsection, the only parameters which have any perceptible impact on the strength of the overhiring effect is the matching elasticity \( \eta \) and bargaining power \( \beta \). Figure 7 compares unemployment rates with and without overhiring for values of \( \eta = \beta \) ranging from 0.30 to 0.75. The impact of overhiring on unemployment becomes progressively stronger as \( \eta = \beta \) increases, as was to be expected since the gap between employment costs and the worker’s marginal revenue product is increasing in worker’s bargaining power \( \beta \).

5 Efficiency

We now consider the efficiency implications of differing degrees of product market competition under individual bargaining. This allows us to make more precise the countervailing effects of monopoly power on the one hand, and the hiring and search externalities on the other. Any setup where firms take their product market power into account will lead to underprovision of goods, and hence underhiring. At the same time firms in individual bargaining settings have an incentive to overhire and thus overproduce (Stole and Zwiebel, 1996), which may counteract some of the monopoly distortions. Thus, one might see individual bargaining as inducing monopolistically competitive firms to ‘self-regulate’ and increase output, bringing them closer to the efficient level implied by perfect competition.22

In the following, we examine the joint efficiency properties of monopolistic competition and individual bargaining.

To focus on this tension between monopolistic underprovision of goods and overhiring due to individual bargaining, we choose per capita aggregate output as the planner’s objective. Maximizing output rather than a utility measure allows us to abstract from the role that increasing our competition measure \( \sigma \) plays in increasing utility via an increase in product variety.23 The social planner maximizes per capita aggregate output, subject to

---

22 See also the discussion in Pissarides (2000) pages 198–201.
23 In the working paper version, we hold demand elasticity across differentiated goods \( \sigma \) constant, and vary competition by varying the number of firms per industry. In this case, maximizing output per capita is equivalent to maximizing utility per capita for a given value of \( \sigma \). Alternatively, one could follow Blanchard and Giavazzi (2003) and add a term which is inversely related to \( \sigma \) to the utility function, which neutralizes any increase in utility from an increase in product variety.
matching costs as aggregate employment. Since \( H = (1 - u) \), per capita output is given by \( A(1 - u) \). Using our definition of labor market tightness we can write economy wide per-period vacancy posting costs as \( \Phi \) so that the per period social welfare function becomes \( A(1 - u) - \Phi u \). To focus on the monopoly, bargaining and matching distortions, we consider the special case where \( b = 0 \) and \( \delta = 0 \). The central planning problem becomes:

\[
\max_{\{u_t, \theta_t\}} \sum_{t=0}^{\infty} \left( \frac{1}{1 + r} \right)^t \{ A(1 - u_t) - \Phi \theta_t u_t + \mu [u_{t+1} - u_t - \chi (1 - u_t) + \theta_t q(\theta_t) u_t] \}
\]

where \( \mu \) denotes the shadow value of an extra vacancy. From the first order condition for labor market tightness we obtain

\[
\mu_t = \frac{\Phi_{\theta_t}}{q(\theta_t)} \frac{1}{1 - \eta(\theta_t)} \quad \text{for all } t
\]

where \( \eta \) denotes the elasticity of the matching function with respect to \( \theta \), i.e. \( \eta = -\frac{\Phi_{\theta_t}}{q(\theta_t)} \). Combining the first order conditions for \( \theta_t \) and \( u_{t+1} \) using the envelope condition and imposing the steady state condition that \( \theta_t = \theta \) and \( u_t = u \), we find an expression for constrained Pareto-efficient labor market tightness similar to that in the decentralized economies:

\[
A = \underbrace{\frac{\eta}{1 - \eta \Phi}}_{\text{firm's cost due to bargaining power}} + \underbrace{\frac{\Phi_{\theta}}{1 - \eta q(\theta)}}_{\text{firm's cost due to monopoly power}} (r + \chi).
\]

By comparing (36) to the equilibrium condition of the monopolistic competition-individual bargaining economy (23), we find two conditions for constrained efficiency.

**Result** When \( b = \delta = 0 \), social efficiency is attained in the monopolistic competition - individual bargaining economy if and only if both:

1. \( \beta = \eta \), the standard Hosios condition;
2. \( \frac{\sigma - \beta}{\sigma - 1} = 1 \), which reflects the monopoly distortion (through \( \sigma \)) and the overhiring effect (via \( \beta \)).

Given that the Hosios condition holds, there are two cases in which the monopolistic competition - individual bargaining economy attains constrained efficiency. First, the monopoly distortion clearly disappears in the perfect competition limit, as \( \sigma \rightarrow \infty \). Second, under imperfect competition (finite \( \sigma \)), constrained efficiency is also attained when workers have all the bargaining power, so that \( \beta = 1 \).\(^{24}\) Effectively, giving workers all the bargaining power allows the overhiring effect to fully counteract the monopoly distortion. The intuition is that when workers have all of the bargaining power, wages are very high and the overhiring effect strongest. At lower levels of bargaining power, \( \beta < 1 \), the hiring externality is diminished, only allowing individual bargaining to partially counteract the monopoly distortion.\(^{25}\)

The search friction, as reflected in the Hosios condition, is neutralized whenever \( \beta = \eta \). Recalling that the RHS of both the efficient equilibrium condition (36) and its individual bargaining counterpart (23) are increasing in \( \theta \), \( \beta \), and \( \eta \), we can infer that for \( \eta < \beta \) the search friction causes unemployment to be above its efficient level. However, for \( \eta > \beta \) the search friction implies a lower-than-optimal level of unemployment.

Hence, our specification of \( \eta = \beta < 1 \) unambiguously leads to inefficiently low employment levels. In this case, the search friction is neutralized, while the net effect of the

\(^{24}\)It should be that in order for social efficiency to obtained under \( \beta = 1 \), the matching function must also be degenerate with elasticity \( \eta = 1 \).

\(^{25}\)Our findings are consistent with Smith (1999), who studies social efficiency for the case of perfect competition and decreasing returns to scale, and Cahuc and Wäsm (2001) who study perfect competition and constant returns to scale.
monopoly and individual bargaining distortions is unemployment which is greater than the efficient level. Similarly, whenever either $\eta < \beta \leq 1$ or $\eta \leq \beta < 1$, both the net effect of the monopoly and individual bargaining distortions and the search friction imply underemployment, leading to an equilibrium level of unemployment which is unambiguously greater than the efficient level. However, for $\beta < \eta < 1$, the search friction implies overemployment whereas the monopoly distortion still suggests underemployment. Given that the two distortions work in opposite directions, it is not clear in this last case whether the level of unemployment will be too low or too high in the decentralized equilibrium as compared to the efficient outcome.

6 Conclusions

The main objective of this paper has been to study the relationship between product market regulation and labor market outcomes. Our main contribution is twofold. First, we develop a dynamic model with imperfect competition and search frictions, which is well suited for the quantitative analysis of the present paper. Our model contains the interesting feature that the standard monopoly distortion of underproduction is partially offset by an overhiring incentive, especially when monopoly power is high.

We then use our model to ask whether the Carter/Reagan deregulation of the late 1970’s and early 1980’s could account for the subsequent decline in US trend unemployment rates. We find that increasing entry costs to their 1978 levels leads to a surprisingly small increase in unemployment of less than two tenths of one percentage point, compared to an increase of two full percentage points in the data.

Thus, while our qualitative finding that product market deregulation has positive repercussions on labor market outcomes is in accordance with the previous literature, we are the first to quantify the effect of deregulation in a fully microfounded dynamic model and conclude that this effect is substantially smaller than previously conjectured.

We do, however, find that product market deregulation could lead to substantial increases in real wages, supportive of political economy arguments in favor of combining labor and product market reform found in Blanchard and Giavazzi (2003). In sum, under individual bargaining, we find that product market reform alone is not sufficient to generate large improvements in labor market outcomes.
References

Appendix A  Proofs

A.1  Proof of Lemma 1

Proof  We need to establish that \( \frac{\partial \theta}{\partial \sigma} > 0 \). Applying the implicit function to equation (23) gives us:

\[
\frac{\partial \theta}{\partial \sigma} = \frac{(1 - \beta) (r + \chi) q'}{\beta \Phi_v \frac{\partial \theta}{\partial \sigma} - \frac{\sigma}{\beta} \frac{\partial \theta}{\partial \sigma}} > 0
\]

The first term and the numerator of the second term are clearly positive since \( \beta \in (0, 1) \) and \( \sigma > 1 \) for equilibrium to exist. For a constant returns to scale Cobb-Douglas matching function \( q' (\theta) < 0 \), so that the denominator is also guaranteed to be positive. ■

A.2  Proof of Proposition 2

Proof  (i) From (25) and applying Lemma 1, it is straightforward to show that \( \frac{\partial \chi}{\partial \sigma} < 0 \) whenever \( q (\theta) + \theta q' (\theta) > 0 \). This latter condition holds for all Cobb-Douglas constant returns to scale matching functions.

(ii) From (18), we obtain

\[
\frac{\partial \chi}{\partial \sigma} = \frac{\partial}{\partial \sigma} \left[ \frac{\beta \Phi_v}{1 - \beta \frac{\partial \theta}{\partial \sigma} (1 - \delta)} \right] > 0
\]

where the last inequality is due to Lemma 1 and the fact that \( q' (\theta) < 0 \) for any CRS Cobb-Douglas matching function. ■

A.3  Proof of Proposition 3

Proof  (i) We need to establish that \( \frac{\partial \theta}{\partial \sigma} \), \( \frac{\partial \theta}{\partial \Phi_v} \), \( \frac{\partial \theta}{\partial \sigma} \), and \( \frac{\partial \theta}{\partial \sigma} \) are all negative. In each case, we apply the implicit function theorem to equation (23), to obtain \( \frac{\partial \theta}{\partial \sigma} = -\frac{\partial [\cdot]}{\partial [\cdot]} \) where \( x \) is the relevant parameter and derivatives are taken with respect to the RHS of (23). It is easy to see that the denominator is positive for all constant returns to scale matching functions, so it remains to establish that the numerator \( \frac{\partial [\cdot]}{\partial [\cdot]} > 0 \) for all parameters \( x \). We obtain:

\[
\frac{\partial [\cdot]}{\partial b} = \frac{\sigma - \beta}{\sigma - 1} > 0
\]

\[
\frac{\partial [\cdot]}{\partial \Phi_v} = \frac{\sigma - \beta}{\sigma - 1} \left( \frac{\beta}{1 - \beta (1 - \delta)} + \frac{1 + r + \chi}{1 - \beta (1 - \delta) q (\theta)} \right) > 0
\]

\[
\frac{\partial [\cdot]}{\partial r} = \frac{\sigma - \beta}{\sigma - 1} \left( \frac{1}{1 - \beta q (\theta)} \right) > 0
\]

\[
\frac{\partial [\cdot]}{\partial \delta} = \frac{\sigma - \beta}{\sigma - 1} \left( \frac{\beta}{1 - \beta (1 - \delta)} \right) > 0
\]

(ii) \( \frac{\partial \theta}{\partial \sigma} \), \( \frac{\partial \theta}{\partial \Phi_v} \), and \( \frac{\partial \theta}{\partial \sigma} \) can be shown to be positive by combining (i) with Lemma 1. For \( \frac{\partial \theta}{\partial \sigma} \) and \( \frac{\partial \theta}{\partial \Phi_v} \) we obtain:

\[
\frac{\partial u}{\partial \sigma} = \frac{\theta q (\theta) (1 - \delta) - \chi \frac{\partial u}{\partial \sigma} (\theta' (\theta) + q (\theta))}{[\chi + \theta q (\theta)]^2}
\]
\[
\frac{\partial u}{\partial \delta} = \frac{\theta q[\theta] \left( 1 - \hat{\chi} \right) - \chi \frac{\partial}{\partial \delta} (\theta q' (\theta) + q (\theta))}{\left[ \chi + \theta q[\theta] \right]^2}
\]

In both cases, the denominator is clearly positive, as is the first term of the numerator. It remains to show that the second term of the numerator is negative: this is indeed the case because we have established in (i) that \( \frac{\partial}{\partial \delta} \chi < 0 \) and because \( \theta q' (\theta) + q (\theta) > 0 \) for CRS Cobb-Douglas matching functions.

(iii) First, note that

\[
\frac{\partial}{\partial \delta} = \Phi' + \frac{1}{\sigma - 1} \left( \frac{\partial}{\partial \beta} \right)^2 + \frac{\Phi}{\sigma - 1} \theta \left( \frac{1}{1 - \beta} \right)^2 - \frac{b}{\sigma - 1}
\]

In the perfect competition limit as \( \sigma \to \infty \), we have that \( \frac{\partial}{\partial \delta} > 0 \). Consider two mutually exclusive cases: \( \frac{\partial}{\partial \delta} \) is either decreasing or increasing in \( \sigma \). In the former case, \( \frac{\partial}{\partial \delta} > 0 \) at \( \sigma \to \infty \) ensures that \( \frac{\partial}{\partial \delta} > 0 \) everywhere. We proceed by first showing that \( \frac{\partial}{\partial \delta} \) is decreasing in \( \sigma \) whenever \( b < \frac{\Phi}{1 - \theta} \). To see this, note that

\[
\frac{\partial^2}{\partial \delta \partial \sigma} = -\Phi \frac{1}{\sigma - 1} + \frac{b}{(\sigma - 1)^2}
\]

Clearly, \( \frac{\partial^2}{\partial \delta \partial \sigma} < 0 \) whenever \( b < \frac{\Phi}{1 - \theta} \). This implies that if \( b < \frac{\Phi}{1 - \theta} \), then \( \frac{\partial}{\partial \delta} < 0 \) and by Lemma 1 \( \frac{\partial u}{\partial \delta} > 0 \). In the latter, we can use that \( \sigma \in (1, \infty) \) and check whether \( \frac{\partial}{\partial \delta} = 0 \) for a threshold value \( \tilde{\sigma} \) which is in the admissible range \( (1, \infty) \). Setting (37) equal to zero and solving for \( \tilde{\sigma} \) gives us:

\[
\tilde{\sigma} = \frac{b \left( 1 - \beta \right)^2 + \frac{\Phi}{1 - \theta} \theta \left( \beta + \beta (1 - \beta) \right) + \frac{\Phi}{\theta} \frac{r + \chi}{1 - \beta}}{\frac{\Phi}{\theta} \frac{r + \chi}{1 - \beta} + \frac{\Phi}{1 - \theta}}
\]

It is straightforward to see that whenever \( b > \frac{\Phi}{1 - \theta} \), then \( \tilde{\sigma} > 1 \) - so that \( \frac{\partial}{\partial \delta} \) goes negative for some admissible value of \( \sigma \in (1, \infty) \). This implies that when \( b > \frac{\Phi}{1 - \theta} \), then \( \frac{\partial}{\partial \delta} \leq 0 \) for all \( \sigma \in [\tilde{\sigma}, \infty) \) and \( \frac{\partial}{\partial \delta} > 0 \) for all \( \sigma \in (1, \tilde{\sigma}) \). The rest of the proof follows by applying Lemma 1.

The ‘Days’ column gives the number of business days necessary to start a new firm, while the ‘Procedures’ column gives the number of entry procedures which new firms must complete. The ‘Index’ column combines the ‘Days’ and ‘Procedures’ measures as \((\text{days} + \text{procedures}/(\text{ave procedures/day}))/2\), so that the indexes’ units are days. The first two columns draw on 1997 data from Logotech S.A., as reported by the OECD [Fostering Entrepreneurship] and by Pissarides. (2001). The fourth column gives Djankov, et al. (2002)’s measure for fees required for entry in 1997, as a percentage of annual per capita GDP.

</table>

The first column summarizes the entry costs of the previous table, by adding up the entry delay (as a fraction of a year) and the fees (as a fraction of annual per capita GDP) and then converting to months by multiplying by 12 to obtain a composite entry cost measure for 1997. The second and third columns present the product market regulation indices reported in Nicoletti and Scarpetta (2000) for 1998 and 1978. The correlation between the 1997 entry-cost based figures and the 1998 index is 0.78. The final column takes the 1978 index values and projects them onto entry costs, using the coefficients obtained from a regression of the 1998 index values onto the 1997 entry costs. This gives us an estimate of 1978 entry costs.

Figure 1: US HP-Trend Unemployment and Regulation Data
Source: BLS and Nicoletti and Scarpetta, 2002
Figure 2: Firm Level Equilibrium Wages and Employment
Figure 3: Contributions of Output Expansion and Overhiring to Equilibrium Tightness: The solid line shows the impact of competition on equilibrium labor market tightness $\theta$ that is solely due to the output expansion effect, that is, when the hiring externality has been shut down by setting $\frac{\sigma - \beta}{\sigma} = 1$. Accordingly, the dashed line shows the impact of competition on $\theta$ that can be attributed solely to the hiring externality, i.e. when the output expansion effect has been shut down by setting $\frac{\sigma}{\sigma} = 1$. 
Figure 4: Entry Regulation and naive Labor Shares. 
Data on compensation/GDP is taken from Gollin (2002), Table 2, column 4. Data on entry regulation is the regulation index of Fonseca et al. (2001), table 2, column 4, multiplied by 5 to convert to days. The negative correlation is highly significant even for the small number of observations. This plot is merely meant to be an illustration of the data.
Figure 5: Baseline Calibration
Figure 6: Quantifying the Overhiring Effect: The solid line shows the impact of competition on equilibrium unemployment (or wages). The dotted line shows how competition affects unemployment (or wages) when the hiring externality has been shut down by setting $\frac{\sigma - \beta}{\sigma} = 1$. 
Figure 7: Quantifying Overhiring for Various $\eta = \beta$ Values: The solid line in each panel shows the impact of competition on equilibrium unemployment. The dotted lines show how competition affects unemployment when the hiring externality has been shut down by setting $\sigma - \beta = 1$. 
Appendix D  Derivation of the Wage Curve: Solving the Differential Equation

From equation (14) we know that the wage curve is described by a differential equation of the form

\[ w(H_i) = (1 - \beta)rv^u + \frac{\sigma - 1}{\sigma} \beta A_i P_i(H_i) - \frac{\beta H_i}{\partial H_i} \frac{\partial w(H_i)}{\partial H_i} \]

which has the solution:

\[ w(H_i) = H_i^\frac{1}{\sigma} \left\{ C + \int_0^{H_i} x^\frac{1}{\sigma} \left[ \frac{1 - \beta}{\beta} rv^u + \frac{\sigma - 1}{\sigma} A_i P_i(x) \right] dx \right\} \]

where \( C \) denotes some constant of integration. The first term of the integrand is easily solved and we can write:

\[ w(H_i) = CH_i^\frac{1}{\sigma} + (1 - \beta)rv^u + \frac{\sigma - 1}{\beta} H_i^\frac{1}{\sigma} A_i \int_0^{H_i} x^\frac{1}{\sigma} P_i(x). \]

The last integral can be solved by parts, where we integrate the \( x \)-term and differentiate the inverse demand function.

\[ \int_0^{H_i} x^\frac{1}{\sigma} P_i(x) = \beta H_i^\frac{1}{\sigma} P(H_i) - \beta \int_0^{H_i} x^\frac{1}{\sigma} \frac{\partial P_i(x)}{\partial x} dx = \beta H_i^\frac{1}{\sigma} P(H_i) - \beta \int_0^{H_i} x^\frac{1}{\sigma} P(x) \frac{\partial P_i(x)}{\partial x} \frac{x}{P_i(x)} dx \]

The demand elasticity is given by \(-1/\sigma\) and so we can write:

\[ \int_0^{H_i} x^\frac{1}{\sigma} P_i(x) = \frac{\sigma}{\sigma - \beta} \beta H_i^\frac{1}{\sigma} P(H_i). \]

which gives equation 15 of the text. The condition to pin down the constant of integration is discussed in Cahuc et al. (2004) who assume that the wage remains finite as \( H_i \to 0 \) which implies \( C = 0 \). This condition is sensible. We know that in the limit of perfect competition \( \sigma \to \infty \) the wage curve must coincide with the standard wage curve of the one-worker firm because the marginal revenue product is constant. Furthermore we also obtain that in the limit of \( \beta \to 0 \) the workers are only paid their reservation wages.
Appendix E  Summary of Equations

• Partial Equilibrium – Firm Level: \( w_i, H_i, Y_i, P_i \)

  1. Technology
     \[ Y_i = A H_i \]

  2. Goods Demand
     \[ \frac{P_i}{P} = \left( \frac{Y_i}{I} \right)^{-\frac{1}{\sigma}} \]

  3. Good Supply
     \[ A \frac{P_i}{P} = \frac{\sigma - \beta}{\sigma - 1} \left( 1 + \tau_p r V^\mu \beta \Phi V \frac{r + \chi}{1 - \beta q(\theta) 1 - \delta} \right) \]

  4. Wage
     \[ w(H_i) = \frac{1}{1 - \tau_I} r V^\mu + \frac{1}{1 + \tau_p} \frac{\beta}{1 - \beta q(\theta)} 1 - \delta \]

  5. Firm Level Employment
     by combining Goods demand and good supply;

• General Equilibrium – Short Run: \( \theta, I, u, H, \tau_I, \tau_p \)

  1. Aggregate Demand and Supply
     \[ I = \frac{P_i}{P} Y_i \]

  2. Symmetry
     \[ P_i = P_j = 1 \]

  3. Beveridge Curve
     \[ (1 - u) \chi = u \theta q(\theta) \]

  4. Constant Labor Force
     \[ H = 1 - u \]

  5. Balanced Budget
     \[ (\tau_I + \tau_p) w(1 - u) = bu \]

  6. Tax Policy
     \[ \tau_I = \tau_p \]

  7. Reservation Wage
     \[ r V^\mu = b + \frac{1 - \tau_I}{1 + \tau_p} \frac{\beta}{1 - \beta} 1 - \delta \]

• General Equilibrium – Long Run: \( \sigma \)

  1. Entry Costs
     \[ \Phi_E = (d + f) I \]

  2. Free Entry Condition
     \[ \Phi_E + \frac{\Phi V}{q(\theta)} H = V^J \]
